Astrology in China

Ho Peng Yoke

In traditional China there was no distinction between astronomy and astrology. The common word *tianwen* covered both. There was also no distinction between astronomy and astrology in Europe before the end of the seventeenth century. According to the *Oxford English Dictionary*, there were two kinds of astrology (a) natural astrology, which involved the calculation and foretelling of natural phenomena, as the

measurement of time, fixing of Easter, predictions of tides and eclipses, and also of meteorological phenomena and (b) judicial astrology, which was the art of judging the reputed occult and nonphysical influences of the stars and planets on human affairs, also known as star divination or astromancy. Since the end of the seventeenth century the term natural astrology was replaced by astronomy and meteorology, while judicial astrology became the astrology commonly known today.

Traditional Chinese astrology included the two elements of natural and occult science. The latter provided the motivating force that enabled Chinese astronomers to produce comprehensive and continuous observational records for almost 2,000 years. These records are of interest to modern astronomers, but they were never made with such an intention. They were meant primarily to enable the emperor to have foreknowledge of future events concerning himself, his imperial household, his senior officials, his empire, his subjects, and foreign countries. Astronomical observations also played a part in the calculation of calendars that gave auspicious and ominous times and dates for various kinds of events in daily life, ranging from wedding ceremonies to having a bath or a haircut. Traditional Chinese judicial astrology differs from its counterpart in Europe in that it was tailored exclusively to serve the emperor and not the individual. Officially this system is now obsolete among the Chinese, but unofficially there were some whispers linking the event of the demise of their Great Helmsman to the 1976 Tangshan earthquake. What is popularly known today as Chinese astrology is not the traditional official Chinese astrology referred to above. Official and popular astrology are two different entities.

Official astrology found its place in the “Astronomical Chapters” of the Chinese Dynastic Histories, beginning with the *Shiji* (Historical Memoirs) of Sima Qian (145–186 BCE). Based on the traditional Chinese belief in the close relationship between heaven (*tian*), earth (*di*), and man (*ren*), the emperor was regarded as the representative of heaven on earth – human actions on the part of the emperor and celestial

phenomena had mutual effects. Chinese astrologers divided the whole sky visible to them, making the stars and asterisms correspond to geographical regions. Almost all of them corresponded to China and only a few smaller asterisms corresponded to neighboring countries.

The Polar Star, which was supposed to remain stationary, was regarded as the counterpart of the emperor in heaven. Perhaps because there was seldom any bright star near the North Pole, and the scope for making predictions would be much more limited when a star was far away from the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course) beyond the reach of the planets, a number of other stars were also designated to represent the emperor. The asterisms in the circumpolar region, known as the *Ziweiyuan* (Purple Subtlety Enclosure), included those that represented the emperor, the empress, the imperial concubines, and the crown prince. There were stars representing his hierarchy of officials, including ministers and military commanders, and there were stars representing the utilities in the palace, for example the kitchen. The region was enclosed by two chains of stars, representing the walls of the Forbidden City. Many parts of the Forbidden City and the circumpolar region shared the same names. Outside the "walls" of the circumpolar region was the Plough (*Beidou*), an important asterism in both Chinese astrology and Daoism.

Next come the asterisms along the ecliptic. Two other special regions, the *Taiweiyuan* (Great Subtlety Enclosure) and the *Tianshiyuan* (Celestial Market Enclosure), were located there. The former again pertained to the emperor, his household, and his official hierarchy and the latter to the general state of economy in his empire. Distributed along the ecliptic were the 28 lunar mansions. They were used to make a wide range of predictions, from flood and drought in the empire to military activities among the border tribal people. The asterisms near the 28 lunar mansions were also significant. The astrologer could observe, for example, four stars in Pisces, called *Yumyu*

(Cloud and Rain) to make a forecast for rain, thus performing the task of the modern meteorologist.

The Sun was the most important astrological object, because it represented the emperor. Solar eclipses and sunspots reflected blemishes on the part of the emperor. Likewise lunar eclipses referred to the empress. The astrologer looked for the presence of planets, comets, and novae near a particular star or asterism to predict an event and where it would happen. The astrologer also noted changes in the color or brightness and scintillation due to atmospheric conditions. He also observed aurora borealis and clouds, noting their color and shape. These were particularly important in the battlefield for gaining advanced information on enemy movements and the outcome of the combat. The astronomical bureau also produced an astrological almanac using the art of *zheri* (calculations of auspicious and inauspicious days) to work out days and times that were auspicious or unlucky for certain events in private and social life, for example having a bath or a haircut, meeting a friend, doing a business transaction, moving house, and holding a wedding ceremony.

There were often occasions when the astrologer was required to give an answer to a specific event, for example when something was lost, when a candidate set out to take the civil examinations, when two armies were facing each other preparing for battle, and so on. There were three sophisticated techniques of divination which fell within the syllabus of candidates taking examinations in the astronomical bureau in the Song Dynasty, namely *taiyi* (Supreme Unity), *dunjia* (Concealing the *jias*), and *liuren* (Six *rens*). These three methods did not restrict themselves to the imperial family and the official hierarchy.

Naturally the common people also wished to have foreknowledge of their individual fate and destiny. The Chinese developed many systems for this purpose, but none of them relied on direct astronomical observation. In the strict sense of the word they hardly qualify to be called astrology. However they generally employed the results of astronomical observations and

calculations by using some or all the elements of year, month, day, and time. Furthermore, at least one of the systems contains traces of Greek and Hindu astrology. There are two systems of fate calculation in general circulation among the Chinese today, namely the *Ziping* method and the *Ziwei doushu* method. These two systems of fate calculation do not rely on direct observations of the stars and in the *Ziwei doushu* horoscopes are worked out without requiring the practitioner to know how to identify the stars that occur in the horoscope.

The history of fate calculation in China is rather obscure as this was not regarded as an orthodox branch of study, and experts writing on this subject often used imprecise language to put off the uninitiated. By the Han period (206 BCE–AD 220), Confucian scholars were talking about three types of human fate (*sanming*). One was endowed during birth and was the only element that could be calculated. One was under the influence of good or evil deeds, and one was governed by catastrophic events that would overrule the first two. It is interesting to draw comparisons with the Han scholars' contemporaries in Europe where the Romans were adopting Stoicism as their state philosophy, believing in the devotion to duty while leaving things to the inevitable. The Chinese had a different belief in life, by talking about three types of life rather than one. To the Chinese it was only the fated life that was predictable, but any predicted event was by no means inevitable. It might be changed according to one's deeds, or by what we nowadays describe as an "act of God". The Chinese system gave encouragement to lead a good life. In this respect it certainly sounded more attractive than Hellenistic astrology.

At first it seems that only the year of birth of the person concerned was taken into account. Even today some Chinese still speak about the "twelve animal cycle" of the years they were born. As time went by, first the month, then the day, and finally the hours (or rather double hour) of birth were gradually included to develop newer systems. The *Ziping* method is one of the most sophisticated systems of fate calculation. It is

attributed to Xu Juyi, said to have lived during the latter half of the tenth century. He was the first to use the time of the day for fate calculation. Many books were also attributed to him, but we do not know exactly which were actually written by him. The most authoritative and comprehensive text that we have on the *Ziping* method is the *Sanming tonghui* (Confluence of the Three Fates) written by Wan Mingyong during the Ming period (1368–1644). Since then the system has frequently been revised to keep abreast with changes in social structure. This can be testified to by the large number of books written on this subject in China, Hong Kong, Japan, and Korea during the past few decades.

However, back in the third century Indian astrology had entered into China when the *Sārdulakarnāvadāna* was translated, introducing the names of the "Seven Luminaries" (Sun, Moon, and the five planets) and the *nakṣatras* (Moonstations). In the year 718 Gautama Siddhārtha translated the *Navagrāha* calendar and introduced the names of two imaginary heavenly bodies, *Rahu* and *Ketu*. Some time afterward a Nestorian named Adam translated a work called *Simenjing* (lit, Book on Four Departments). This book has long been lost, but it could have been a translation of Ptolemy's *Tetrabiblos*, according to recent Japanese authorities on the subject such as Kiyoshi Yabuuchi. Michio Yano has suggested that another book with the title *Duliyusijing* carried the name of Ptolemy in a corrupted form. Hellenistic astrology also went from Persia to China through Korea. Another important route taken by Hellenistic astrology was through India, where it was modified under the influence of Hindu astrology. Tantric monks played an important role in the introduction of this form of astrology to China. Amoghavajra (705–774) produced a book known under its abridged title *Xiuyaojing* (Book on the *Nakṣatras* and the Luminaries), in which the 12 signs of the zodiac appeared for the first time in China. Thus by the eighth century imported systems of astrology with Hellenistic and also often Hindu roots had become quite popular. A number of actual horoscopes cast during the Tang period are preserved

in the *Qinding gujin tushu jicheng* (Imperial Encyclopedia), edited by Chen Menglei et al. in 1726.

Changes took place when new ideas came into the same melting pot with something that was originally in it. Traditional Chinese star names and astrological terms were adopted by the new imports. Gradually the latter became sinicized. One can hardly notice the Hellenistic and Hindu origin of the *Ziwei doushu system* by looking at its name alone. We do not know when exactly the term “*Ziwei*” was first used here. During the Tang period several names were used; among them was the term *Taiyi*. The “star” *Taiyi* played the same role as the “star” *Ziwei* in the modern system, and both have somewhat similar reference to the occupant of the most supreme position below or above. The term *Ziwei doushu* first appeared in the title of a book incorporated in the Daoist *Tripitaka*, the *Xu Daozang* in 1607. Similarly traditional fate calculation methods were at the same time influenced by imported cultures. The Ziping system for example employs a cycle of 12 phases, reminiscent of the 12 *Nidā nas* in Buddhism.

Astrology in India

Vijaya Narayan Tripathi

In India, astrology, *Jyotiṣa*, is defined as *Jyotiṣam sūryādi grahāṇām bodhakamśāstram*, the system which explains the influences of the sun, moon, and planets.

Indian astrology came explicitly to light around 1200 BCE, when the monk Lagadha compiled the *Vedānga-Jyotiṣa* on the basis of *Vedas*, in which lunar and solar months are described, with their adjustment by *Adhimāsa* (lunar leap month). *ṛtus* (seasons), years, and *yugas* (eras) are also described. Twenty-seven constellations, eclipses, 7 planets, and 12 signs of the zodiac were also known at that time.

In the period from 500 BCE to the beginning of the Christian era some texts were written on the subject of astrology. Nineteen famous sages composed their *Siddhāntas* (texts). *Candra-prajñapti*, *Sūrya-prajñapti*, and *Jyotiṣakaraṇḍaka* were written. The *Sūryasiddhānta*, the ancient text of Indian astrology, was composed around 200 BCE.

In the first five centuries of the Christian era, there were some important contributions by Jain writers. *Angavijjā* is a large collection about *Śakuna* (omens). *Kālaka* and *ṛsiputra* also contributed around this time. At the end of the fifth century, Āryabhaṭa I mentioned in his text *Āryabhaṭīya* that the sun and stars are constant and that day and night are based on the movement of the earth.

The period AD 500–1000 was very productive. Lallācārya, the disciple of ► [Āryabhaṭa](#), composed two texts – *Śiṣyadhīvr̥dhi* and *Ratnaśa* – dealing with mathematical theories. The astrologer ► [Varāhamihira](#) composed several texts, and his son Pṛthuyasā composed a brief horary called *ṣat-Pañcāśikā*. Bhāskaraṇḍaka I wrote a commentary on the *Āryabhaṭīya* in the seventh century, and ► [Brahmagupta](#) composed the *Brāhmasphuṭasiddhānta* and the *Khaṇḍakhādya* around AD 635. Other scholars

wrote commentaries on the texts of their predecessors and independent texts of their own.

In 1000–1500, there was a great deal of enhancement to the literature concerning the construction of astronomical instruments for observation. In the twelfth century, Bhāskara composed the famous text *Siddhāntaśiromaṇi*. The Līlāvātī of Rājāditya is another of the texts of that century. In the fifteenth century, Keśava wrote more than ten books, and his son Gaṇeśa composed the *Grahalāghava* at the age of 13.

Many more texts and commentaries were written from the sixteenth century onward. A few noteworthy ones are: *Tājikanīlakaṇṭhī* of Nīlakaṇṭha (sixteenth century), *Meghamahodaya* by Meghviṇayagaṇi (seventeenth century), *Janmapatrīpaddhati* by Lābhacandragāṇi (eighteenth century), and the nineteenth century works of astrologer Bāpūdeva Śāstri.

A knowledge of *pañcāṅga* is a prerequisite to understanding the subject of astrology. This is the fivefold system of *tithi* (lunar day), *vāra* (weekday), *nakṣatra* (asterism), *yoga* (sum of the solar and lunar longitudes), and *karaṇa* (half lunar day). *Tithi*, the lunar date, is the duration of time in which the Moon moves 12°. The 15 *tithis* of the white fortnight (from new moon to full moon) are:

1. *Pratipadā*
2. *Dvītyā*
3. *Tṛtīyā*
4. *Caturthī*
5. *Pañcamī*
6. *ṣaṣṭhī*
7. *Saptamī*
8. *Aṣṭamī*
9. *Navamī*
10. *Daśamī*
11. *Ekādaśī*
12. *Dvādaśī*
13. *Trayodaśī*
14. *Caturdaśī*
15. *Pūrṇimā* ($15 \times 12^\circ = 180^\circ$)

In the black fortnight (from full moon to new moon), the 15th day is called *Amāvasyā* and the remainder are the same as above. *Tithis* are

Astrology in India, Table 1 Twenty-seven *nakṣatras* (asterisms)

<i>Ḳṛttikā</i>	<i>Rohiṇī</i>
<i>Mṛgaśīras</i>	<i>Ārdrā</i>
<i>Punarvasu</i>	<i>Puṣya</i>
<i>Āśleṣā</i>	<i>Maghā</i>
<i>Pūrvāphālgunī</i>	<i>Uttarāphālgunī</i>
<i>Hasta</i>	<i>Citrā</i>
<i>Svātī</i>	<i>Viśākhā</i>
<i>Anurādhā</i>	<i>Jyēṣṭhā</i>
<i>Mūla</i>	<i>Pūrvāṣāḍhā</i>
<i>Uttarāṣāḍhā</i>	<i>Śrōṇā</i>
<i>Śraviṣṭhā</i>	<i>Śatabhiṣaj</i>
<i>Pūrvā-Bhādrapada</i>	<i>Uttarā-Bhādrapada</i>
<i>Revatī</i>	<i>Aśvīnī</i>
<i>Bharaṇī</i>	

classified into five groups: *Nandā* (*tithis* 1,6,11), *Bhadrā* (2,7,12), *Jayā* (3,8,13), *Riktā* (4,9,14), and *Pūrṇā* (5,10,15).

The seven *vāras* (weekdays) are based on the names on the *grahas*: Sun, Moon, Mars, Mercury, Jupiter, Venus, and Saturn.

There are 27 *nakṣatras* (asterisms) bifurcating the ecliptic into 27 parts, each of 13.33° . These are mentioned in Table 1.

The ecliptic is again bifurcated into 12 parts through *Rāśis* (signs, each of 30°). The 12 signs are equal to 27 *nakṣatras*, or 1 sign = 2.25 constellations. For example, *Aśvīnī*, *Bharaṇī*, and one-quarter of *Ḳṛttikā* make the sign *Meṣa* (Aries). The remaining three quarters of *Ḳṛttikā*, *Rohiṇī*, and half of *Mṛgaśīra* make the sign *Vṛṣa* (Taurus). The same pattern holds true for the other signs: *Mithuna* (Gemini), *Karka* (Cancer), *Singha* (Leo), *Kanyā* (Virgo), *Tulā* (Libra), *Vṛścika* (Scorpio), *Dhanu* (Sagittarius), *Makara* (Capricorn), *Kumbha* (Aquarius), and *Mīna* (Pisces). Thus 27 constellations represent 12 signs.

Yoga is the sum of the solar and lunar longitudes. If the sum of their degrees is between 0 and 13.33° , that is called *Viṣkambha Yoga* – from there until 26.66° it is *Prīti* – up to 40° it is *Āyusmāna*. The remaining yogas are *Saubhāgya*, *Śobhana*, *Atigaṇḍa*, *Sukarmā*, *Dhṛti*, *Śūla*, *Gaṇḍa*, *Vṛdhi*, *Dhruva*, *Vyāghāta*, *Harṣaṇa*, *Vajra*, *Siddhi*, *Vyatīpāta*, *Varīyāna*, *Parigha*,

Astrology in India, Chart 1 Ascendant as sketched in northern India

Astrology in India, Chart 3 Ascendant as sketched in eastern India (West Bengal and Orissa)

Astrology in India, Chart 2 Ascendant as sketched in southern India

Astrology in India, Chart 4 Navamanśa chart

Śiva, Siddha, Sādhyā, Śubha, Śukla, Brahma, Aindra, and Vaidhṛti ($13.33^\circ \times 27 = 360^\circ$).

Karaṇa (constant or moveable) is the half part of the *tithi*. Constant *Karaṇa Śākuna* belongs to the second half of *Caturdaśī Catuspada* and *Nāga* to that of *Āmāvasyā* in the black fortnight, while *Kistughna* exists in the first half of the *Pratipada* of the white fortnight in every lunar

month. The remaining 14.5 *tithis* of the white and 13.5 *tithis* of the black fortnight contain eight rounds of seven moveable *Karaṇas*: *Bava, Bālava, Kaulava, Taitila, Gara, Vaṇija, and Viṣṭi*.

The subject matter of astrology may be divided into five groups: *Samhitā, Siddhānta, Jātaka, Prasāna, and Śākuna*. In ancient India, *Samhitā* was the miscellaneous collection of astrological materials out of which the remaining four grew.

Astrology in India, Table 2 Positions of *grahas* (planets) on 21 March 1994 at 6:02 a.m. at Varanasi

<i>Grahas</i> (planets)	Sun	Moon	Mars	Mercury	Jupiter	Venus	Saturn	<i>Rāhu</i>	<i>Ketu</i>
<i>Rāśi</i> (sign)	11	2	10	10	6	11	10	7	1
<i>Anśa</i> (degree)	6	15	16	9	23	22	8	3	3
<i>Kalā</i>	21	7	57	51	19	13	21	3	3
<i>Vikalā</i>	27	45	18	17	40	8	21	44	44

Siddhānta or *Gaṇita* refers to mathematical calculations about time, distance, and position of the planets. On the basis of the proper positions of 12 signs and 9 planets, a chart containing 12 chambers may be sketched. In northern, southern, and eastern India, astrologers sketch Charts 1, 2, and 3 which are called *Janmāṅga* or ascendant.

Jātaka (native) is the person about whom a prediction is made on the basis of a birth chart. Twelve houses represent the health, wealth, brother/sister, mother, offspring, diseases/enemies, wife/husband, death, fate, father, income, and expenses, as in Chart 1. *Daśās* (periods) are defined in numerous ways. The period of any planet becomes favorable or harmful according to its position and power in the horoscope (Chart 4).

There are many other astrological methods in India. As an example, in the Kerala system, numbers are assigned to alphabets, and the astrologer advises the person to say the names of a flower, river, or god on which the calculation depends.

Astrology is applied to many aspects of Indian life. There are rules concerning times for traveling, planting, and building. Favorable times for the preparation of medicines and treatment are also prescribed (Table 2).

Astrology in Islam

Richard Lemay

A few considerations about the historical development of the term and concept of astrology as an intellectual discipline are in order, so as to avoid the many misconceptions that prevail in this field of historical enquiry.

The first question concerns the terminology applicable in medieval Arabic culture. What we consider astrology in our epistemology has very little connection with its medieval definition. Horoscope-making and interpreting are of course part of the game but with a rather remote bearing on its definition as a science in medieval eyes. In the mind of medieval Arab writers there is but one science of the sky with the moving bodies set in it. It was called *ʿilm an-nujūm* (science of the stars) and it consisted of two distinct treatments of the subject matter of the heavens: a purely mathematical one or *ʿilm al-falak* corresponding to our astronomy, and a humanistic but rather

conjectural one which aimed at deducing from the celestial motions their probable significance for the evolution of human affairs, more directly what we now call astrology. The name for this latter discipline was *ʿilm aḥkām an-nujūm* (science of the judgments of the stars): hence the new term *scientia iudiciorum* or judicial astrology in medieval Latin culture. The two methods of treatment were indissolubly linked in the overall picture, and it must be further stressed that the dominating interest of medieval Arabic civilization was the “science of the judgments of the stars.” On the practical level, the second portion of this dichotomy was considered an art, and the term *ṣanʿa* applied to it was the equivalent of any other trade or profession.

There were three levels through which Arab authors would approach the study of astrology: a first level through the general science of the stars which could be a predominantly philosophical enquiry bordering on what may be actually labeled cosmology. A second level, purely mathematical, consisted of the consideration of the movements of the spheres, of the celestial bodies they contained, and of phenomena affecting them. This approach corresponded more closely to our astronomy. A third level was in the extension of the above observations to judge their probable impact upon human affairs. The technique of these judgments (*aḥkām*) was determined according to very intricate rules embodied in the age-old lore of astrology proper: but the three levels were considered together to constitute the one science of the stars (*ʿilm an-nujūm*).

This tripartite structure of the science of the heavens among medieval Arab writers was not entirely their creation, for the historical event of early Arab conquests of the entire Middle East had put the young Arab civilization in direct contact with both the still active Hellenistic (Alexandrian) world of thought thriving in Egypt and in the Eastern Mediterranean on the one hand, and the very ancient Babylonian, Persian, and even Hindu cultural traditions on the other. In examining medieval Arabic astrology it is wise to keep in mind these major cultural orientations varying in importance according to

the stages of those historical convergences. During the first century of Arab conquests, which corresponds roughly with the rule of the Umayyad Caliphate of Damascus (660–750), the predominant cultural influence came from Syria and Egypt, in which Hellenistic culture and further Christianized Hellenism dominated. Even so, the impact of Greek learning was not directly linked at first with classical Greek science or philosophy, but rather with its late Hellenistic phase heavily marked by neo-Platonic and Alexandrian speculation or mysticism (hermeticism). The full force of the Greek example of learning and of its formative impact on Arabic astrology emerged only under the Abbasid rule (beginning in 750), tentatively at first under al-Mansūr (754–775) and Harūn al-Rashīd (786–809), but dramatically under ► al-Maʾmūn (813–833) through the direct importation of the works of thinkers and of scientists such as Aristotle in physics and cosmology, and of Ptolemy in astronomy/astrology. Al-Maʾmūn established at Baghdad an astronomical observatory and *Bayt al-ḥikma* (House of Wisdom) endowed with a great library. It was because of these favorable conditions that the science of astrology, like philosophy and medicine, took its definite hue in Arab literature under the label of *falsafa* (a transliteration of the Greek term philosophy). Maʾmūn’s patronage brought scientists and philosophers from all over the Muslim empire. It was likely in the midst of this intellectual fervor that the greatest writer in Arab astrology, Abu Maʾshar, came from his native Balkh in Khurāsān (now Afghanistan) to settle in Baghdad. Although Abū Maʾshar’s major work, the *Kitāb al-mudkhal al-kabīr* (Greater Introduction to Astronomy, AD 848) was completed during the generation following the death of al-Maʾmūn (AD 833), its success in molding the framework of Arab astrology that merged the diverse astrological traditions of Greece, Persia, and India must be ascribed to the lively interest in *falsafa* engendered by al-Maʾmūn’s sponsorship. With Abū Maʾshar’s work, Arab astrology acquired its definitive structure, the result of a syncretism of all Middle East traditions under the umbrella of Aristotelian cosmology and Ptolemaean astronomy/astrology.

Abū Ma'shar came to be quoted as the authority, even by those who criticized him (► *al-Bīrūnī*, Ibn Ridwān). His *Kitāb al-mudkhal al-kabīr* became the “bible” of Arabic astrology because it buttressed the science with a theoretical foundation based on *falsafa*, with Persian and Hindu traditions more or less coherently merged into it. Yet it provided only the introductory theory of astrology as part of the science of Nature. Further extension of the science of judgments of the stars to the full range of human affairs was seen as a kind of adjustment to their inevitable cosmic framework. Arabic astrological science came to include these five principal divisions.

1. A theoretical or introductory part (*mudkhal*) exploring its foundations in physical science and metaphysics. Here Abū Ma'shar's *Kitāb al-mudkhal al-kabīr* shared ultimate authority together with Ptolemy's *Tetrabiblos*.
2. A section dealing with Nativities (*mīlād*, *mawālīd*) which consisted of drawing up diagrams (horoscopes) of the state of the sky at the time of any beginning. Its most natural occasion was at the time of birth (hence “nativities”), or even of conception when possible, and it would be held as an indication of the probable unfolding of the various life circumstances of the individual person or object for whom it was drawn up. It is not without interest to recall that before the establishment of individual identity status such as birth registers, beginning with the sixteenth century in Europe, natal horoscopes constituted the most reliable record of the chronological span of individual lives. Not every one was born of sufficiently wealthy or honorable stock to be able to afford this luxury. Abū Ma'shar himself lamented the fact that he did not know the exact date of his birth, to compensate for which he had drawn up for himself a “general” (approximative) horoscope.
3. Interrogations (*masā'il*) which dealt mostly with enquiries about objects hidden or lost, innermost thoughts or intentions, purposes, etc. A kind of oracle, it aimed to assist individuals in their important decision making or help recover missing objects.
4. Elections or Choices (*ikhtiyārāt*), which were concerned with determining the most favorable moment for starting on important undertakings, such as the construction of cities, opening of hostilities in wartime, investiture or inauguration, or starting on a journey.
5. Weather predictions or meteorology, which were almanacs which astrologers operating for courts, cities, or institutions like universities would issue at the beginning of each new year, as part of their official duties. Weather predictions were of course a prime concern in any predominantly agrarian society.

The art or trade of the astrologer on the other hand was referred to by the term *ṣan'a* and was treated like any other profession. More specialized applications of astrological science still flourished beside the main stream, particularly in medicine where some Greek treatises of Hippocrates (*On Airs* and *De hebdomadibus* for instance) and Galenic ones about duration of pregnancy were merged into astrological prognostication (*taqdimat al-ma'rifa*) and enjoyed enormous vogue among physicians. Finally all sorts of “predictions” or “interpretation of signs” proliferated in a number of specialized practices of quackery into which some pretense of astrological judgments was introduced. Some of these are chiromancy (interpretation of lines of the hand), spatulomancy (interpretation of form of shoulder blade), and sternutomancy (on sneezing).

An influential sequel to Abū Ma'shar's *Greater Introduction* appeared by Aḥmad ibn Yūsuf, a physician, mathematician, and astrologer of the Tūlūnid era (870–904) in Egypt. Aḥmad wrote a chronicle of this Turkish dynasty and he authored several works of mathematics. He put together an astrological compendium which he entitled *Kitāb aṭh-ṭhamara* (Liber Fructus). Since it comprised 100 short propositions, each one accompanied by a substantial commentary, it came to be designated as *Centiloquium*. In fact its major doctrines are taken straight from Abū Ma'shar's *Kitāb al-mudkhal al-kabīr*. The very passage in Abū

Ma'shar's work which probably gave Aḥmad the inspiration for his forgery is met in a special section of the magnum opus (III, 1–2) where ► [Abū Ma'shar](#) enumerates the six benefits to be derived from astrological science, the most alluring of which are the “fructus” (*tamara*) to be anticipated from it.

These two works by Abū Ma'shar and by Ibn Yūsuf, respectively, the second in the footsteps of the first, influenced the West from the time of their translation into Latin during the twelfth century until the demise of astrology as a science in the Scientific Revolution of early modern times. The nature, influence, and significance of Arabic astrology in the East and the West during the Middle Ages were polarized around the success of these two major works.

Astronomical Instruments in India

Yukio Ōhashi

Astronomical knowledge in India can be traced back to the Vedic literature (ca. 1500–500 BCE), the earliest literature in India, but no astronomical instrument is mentioned there. Naked eye observations of the sun, moon, and lunar mansions were carried out. It is not clear whether five planets were observed or not.

There is a class of works called *Vedāṅga*, probably composed toward the end of the Vedic period, which is regarded as auxiliary to the Veda. It consists of six divisions, including *Jyotiṣa* (astronomy) and *Kalpa* (ceremonial). The *Kalpa* further consists of four divisions, including *Śulba* (method of the construction of the altar). The earliest astronomical instruments in India, the gnomon and the clepsydra, appear in the *Vedāṅga* literature.

The gnomon (Sanskrit: *śaṅku*) is used for the determination of cardinal directions in the *Kātyāyana-śulbasūtra*. A vertical gnomon is erected on a leveled ground, and a circle is drawn with a cord, whose length is equal to the height of the gnomon, with the center the foot of the gnomon. At the two points where the tip of the gnomon-shadow touches the circle, pins are placed, and they are joined by a straight line. This line is the east-west line.

The annual and diurnal variations of the length of the gnomon-shadow are recorded in the political work *Artha-śāstra* of Kauṭilya, the

Buddhist work *Śārdūlakarṇa-avadāna*, and Jaina works such as the *Sūrya-prajñāpti*. These records seem to be based on observations in North India.

The clepsydra is mentioned in the *Vedāṅga-jyotiṣa*, the *Artha-śāstra*, and the *Śārdūlakarṇa-avadāna*. It was like a water jar with a hole at its bottom from which water flowed out in a *nāḍikā* (one-sixtieth of a day).

Toward the end of the *Vedāṅga* astronomy period, certain Greek ideas of astronomy and astrology had some influence in India from the second to the fourth century AD. After that, Hindu astronomy (*Jyotiṣa*) established itself as an independent discipline, and several fundamental texts called *Siddhāntas* were composed. I call this period, from about the end of the fifth to the twelfth centuries AD, the classical *Siddhānta* period. The main astronomers who described astronomical instruments are ► *Āryabhaṭa* (b. AD 476), ► *Varāhamihira* (sixth century AD), ► *Brahmagupta* (b. AD 598), Lalla (eighth or ninth century AD), ► *Śrīpati* (eleventh century AD), ► *Bhāskara II* (b. AD 1114), and the anonymous author of the *Sūrya-siddhānta*. The *Siddhāntas* composed by Brahmagupta, Lalla, Śrīpati, and Bhāskara II contain special chapters on astronomical instruments entitled *Yantra-adhyāya*. The Sanskrit word *yantra* means instrument. No observational data are recorded in the *Siddhāntas*, and the extent of actual observations in this period is controversial. Roger Billard maintained that astronomical constants in the *Siddhāntas* were determined by actual observations, while David Pingree argued that they were exclusively borrowed from Greek astronomy. In this connection, we should note that the method of determination of astronomical constants by

means of observations was correctly explained by Bhāskara II. Let us see the instruments in this period.

The gnomon (*śaniku*) was continually used in this period. The theory of the gnomon – such as the relationship between the length of gnomon-shadow, the latitude of the observer, and time – was developed in this period, and a special chapter called *Tripraśna-adhyāya* in the *Siddhāntas* was devoted to this subject. Trigonometry, invented in India, was fully utilized for this purpose.

The staff (*yaṣṭi-yantra*) is a simple stick, used to sight an object. There are some variations of the staff, such as V-shaped staffs for determining angular distance with the help of a graduated level circle.

The circle instrument (*cakra-yantra*) is a graduated circular hoop or board suspended vertically. The sun's altitude or zenith distance is determined, and time is roughly calculated from it. Variations of the circle instrument are the semicircle instrument (*dhanur-yantra*) and the quadrant (*turya-golaka*).

A circular board kept horizontally with a central rod is the chair instrument (*pīṭha-yantra*), and a similar semicircular board is the bowl instrument (*kapāla-yantra*). They determine the sun's azimuth, and time is roughly calculated from them.

A circular board kept in the equatorial plane is the equator instrument (*nāḍīvalaya-yantra*). It is a kind of equatorial sundial. The combination of two semicircular boards, one of which is in the equatorial plane, is the scissors instrument (*kartarī-yantra*). Its simplified version is the semicircular board in an equatorial plane with a central rod.

Astronomical

Instruments in India,

Plate 1 The armillary sphere in the Government Museum, Jaipur (a), and in Rao Madho Singh Museum, Kota (b), (both in Rajasthan)

Astronomical Instruments in India, Plate 2 The clepsydra preserved in Rao Madho Singh Museum, Kota (Rajasthan)

The Indian armillary sphere (*gola-yantra*) was based on equatorial coordinates, unlike the Greek armillary sphere, which was based on ecliptical coordinates, although the Indian armillary sphere also had an ecliptical hoop. Probably, the celestial coordinates of the junction stars of the lunar mansions were determined by the armillary sphere since the seventh century or so (see Plate 1). There was also a celestial globe rotated by flowing water.

The clepsydra (*ghaṭī-yantra*) was widely used until recent times. Unlike the clepsydra of the *Vedāṅga* period, which was the outflow type of water clock, the clepsydra of this period is a bowl with a hole at its bottom floating on water. Water flows into the bowl, and it sinks after a certain time interval. The Chinese Buddhist traveler Yijing (AD 635–713) recorded the actual use of the clepsydra of this type. The clepsydra can be seen in use in a museum at Kota (Rajasthan) (see Plate 2). Several astronomers also described water-driven instruments such as the model of fighting sheep.

Astronomical Instruments in India, Fig. 1 *Phalaka-yantra*

**Astronomical
Instruments in India,
Fig. 2** *Dhruva-bhrama-
yantra*

A

The board instrument (*phalaka-yantra*) invented by ► **Bhāskara II** is a rectangular board with a pin and an index arm, used to determine time graphically from the sun's altitude (see Fig. 1). This is an ingenious instrument based on the Hindu theory of the gnomon.

The astrolabe was introduced into India from the Islamic world at the time of Fīrūz Shāh (r. AD 1351–1388) of the Tughluq dynasty. Fīrūz Shāh's court astronomer Mahendra Sūri composed a Sanskrit work on the astrolabe entitled *Yantra-rāja* (King of Instruments, the Sanskrit term for the astrolabe) in AD 1370. This is the earliest Sanskrit work on Islamic astronomy. Use of the astrolabe rapidly spread among some Hindu astronomers, and Padmanābha (AD 1423) and Rāmacandra (AD 1428) described the astrolabe in their works.

Some new instruments were made in the Delhi Sultanate and Mughal periods. Padmanābha invented a kind of nocturnal instrument called *dhruva-bhrama-yantra* (polar rotation instrument) (see Fig. 2). It was a rectangular board with a slit and a set of pointers with concentric graduated circles. Adjusting the slit to the direction of α and β Ursae Minoris, time and other calculations could be obtained with the help of pointers. Its backside was made as a quadrant with a plumb and an index arm. Thirty parallel lines were drawn inside the quadrant, and trigonometrical calculations were done graphically. After determining the sun's altitude with the

Astronomical Instruments in India, Fig. 3 *Pratoda-
yantra*

help of the plumb, time was calculated graphically with the help of the index arm.

Later, Cakradhara described the quadrant as an independent instrument, and a more exact method to calculate time was explained.

Astronomical Instruments in India, Plate 3 Jai Singh's observatory at Jaipur (Rajasthan), Viewed from its larger Samarāt-yantra

Astronomical Instruments in India, Plate 4 The larger Samarāt-yantra in Jai Singh's observatory at Jaipur

Another new type of instrument in this period was the cylindrical sundial called *kaśā-yantra* (whip instrument) by Hema (late fifteenth century AD) or *pratoda-yantra* (whip instrument) by Ganeśa (b. AD 1507) (see Fig. 3). It is a cylindrical rod having a horizontal gnomon and graduations of time according to the vertical shadow below the gnomon.

The quadrant and the cylindrical sundial exist in the Islamic world also, but the possibility of their influence on these Indian instruments is still to be investigated.

The Mahārāja of Jaipur, Sawai Jai Singh (AD 1688–1743), constructed five astronomical

observatories at the beginning of the eighteenth century. The observatory in Mathura is not extant, but those in Delhi, Jaipur, Ujjain, and Banaras are (Plate 3). There are several huge instruments based on Hindu and Islamic astronomy. For example, the *samarāt-yantra* (emperor instrument) is a huge sundial which consists of a triangular gnomon wall and a pair of quadrants toward the ► east and west of the gnomon wall. Time has been graduated on the quadrants (Plates 4).

By this time, European astronomy had begun to be introduced into India, and Jai Singh had certain information about it. The earliest

Astronomical Instruments in Japan

Nakamura Tsuko

Beginning around the sixth century, Japan was under the strong cultural influence of China (via Korea), and astronomy was no exception. Although by the beginning of the eighth century an institutional form of the Chinese Astronomical Office had been introduced into the Japanese court government along with primitive gnomons and water clocks, astronomy as a science did not become part of Japanese society, and only the astrological aspects of Chinese astronomy survived. This situation continued for many centuries throughout medieval times, partially due to the domestic turmoil caused by frequent civil wars. It was not until after the shogun Tokugawa Ieyasu finally ruled over Japan in 1615 that the Japanese people could afford to nurture their own culture. In the mid-sixteenth century, European astronomy was first brought by the Christian missionaries from Portugal and Spain, though their influence did not last long. The reason was that the shogunal government ousted them because it suspected that the true aim of the Christian missionary activities in Japan was political occupation. Thereafter, import of foreign books relating to the Western religion and culture was strictly prohibited, and only Dutch traders were allowed to come to Nagasaki.

Astronomy as a science and the development of astronomical instruments started from the

seventeenth century in Japan (Nakayama, 1969). In the 1680s, ► [Shibukawa Harumi](#) was nominated to be the first astronomical officer of the shogunate, after the government adopted his proposed new luni-solar calendar. For observations in this calendar reform, he made a gnomon with an apparatus to sharpen the blurred shadow of the sun. He also constructed an armillary sphere of 90 cm in diameter which was a simplified version of the traditional Chinese armillary sphere, and he measured the positions of many stars with it to produce the first Japanese star map. His compiled star catalog reveals that the observational error of his armillary sphere was about half a degree, though this instrument has since been lost. The only existing armillary sphere actually used for astronomical observations is the one preserved at Sendai City Observatory, which is about 100 cm in diameter and made of bronze with scales of half a degree interval.

After Harumi, there was no one to inherit and develop his scientific achievements till the advent of the eighth shogun Tokugawa Yoshimune in the 1710s. He was deeply interested in the natural sciences and made efforts to organize and cultivate the study of science. In 1729 he relaxed the ban of importing Chinese books written by Jesuit priests in China and also allowed Dutch interpreters at Nagasaki to learn Dutch books. This was because, he recognized the superiority of Western astronomy over Chinese traditional astronomy and planned a calendar reform using Western astronomy. He took some astronomers and mathematicians to the shogunal astronomical office and ordered an optician from Nagasaki to devise good telescopes for astronomical observations. Yoshimune himself was also engaged in astronomical observations by inventing a few new armillary spheres and transit quadrants. Despite Yoshimune's enthusiasm, his intended calendar reform was unsuccessful, due to the poor abilities of the shogunal astronomers and the opposition of the court astronomers based at Kyoto.

Because of the hereditary system for the position of the shogunal astronomers, the scholastic ability of some amateur astronomers overpowered that of the shogunal astronomers

around the end of the eighteenth century. The shogunate eventually summoned the two civil astronomers of Osaka, Takahashi Yoshitoki and ► **Hazama Shigetomi**, to take leadership for a new calendar reform as the shogunal astronomers (Watanabe, 1987). The former was superior in theoretical astronomy and the latter in developing astronomical instruments. Before their nomination to the position, they already possessed some knowledge of Copernican and Keplerian theories of planetary motions learned through Sino-Jesuit astronomical books, and they also devised accurate astronomical instruments by consulting *Lingtai Yizhi* (Astronomical Observatory Instruments, by Verbiest et al. (1674)). This book described with many detailed illustrations the structure and usage of several new astronomical instruments constructed by the Jesuit astronomers serving the Qing Dynasty, which were hybrids of the traditional Chinese instruments and European ones invented by people such as Tycho Brahe.

The principal instruments among the ones produced by the Takahashi-Hazama group were the quadrant of 195 cm in radius with a telescope and the wire meridian transit of about 3.6 m in height, both installed at the shogunal observatory of Edo (ancient Tokyo). The quadrant was equipped with a diagonal subscale, which was reinvented by Brahe, so that it could measure stellar positions (altitudes) with an error of 10–15 arcsec. For measuring the meridian-transit time of stars, they used an astronomical pendulum clock which was also devised by the Takahashi-Hazama group with hints from *Lingtai Yizhi*. This astronomical clock could give stellar-transit timings with an accuracy of about 1 s. Although several such astronomical clocks made before 1850 still exist, all the instruments used at the shogunal observatory of Edo were lost or destroyed in the disorder of the Meiji Restoration in 1868.

► **Ino Tadataka**, one of Takahashi's disciples, conducted a large-scale land survey all over the Japanese archipelago starting from 1800. This was the first scientific expedition of geodesy conducted in Japan. Although the methods of mapmaking and measuring

Astronomical Instruments in Japan, Fig. 1 Transportable wire meridian transit used by Ino Tadataka in his land survey expedition of Japan (Otani, 1932)

instruments by Ino were not innovative ones, his 16-year-long enthusiasm led him to complete the entire map of Japan. For the fieldwork, he designed and constructed a few portable quadrants for astronomical latitude observations; the most frequently used one has the quadrant whose radius is 115 cm. Analysis of his field notes shows that the accuracy of single observations with this quadrant was about 20–30 arcsec. Ino also used a transportable wire transit (Fig. 1) for observing the meridian passage of stars along with a pendulum clock. This transit instrument was not useful for determining longitudes of triangulation points because of the lack of a precise chronometer, but it was mainly used for maintaining the local time. As for azimuth measurements, he devised semicircular magnetic compasses with an alidade. His 57-volume azimuthal catalog of more than 2,200 triangulation points reveals that the typical error of Ino's azimuth measurements was 5'. All of those instruments are now preserved at Ino's memorial museum. Astronomers of the Takahashi-Hazama group including Ino did not adopt the Vernier subscale but exclusively adhered to the diagonal subscale for precise measurements.

Telescopes

Telescopes in Japan have a fairly long history. As far as historical records tell us, the first introduction of a telescope into Japan goes back to 1613, when a captain of the British East India Company offered a telescope to the first Shogun Tokugawa Ieyasu for trade promotion; this telescope does not seem to exist now. The earliest existing telescope in Japan was the one owned by Tokugawa Yoshinao, the ninth prince of Ieyasu (now preserved at the Tokugawa Fine Arts Museum). Since Yoshinao died in 1650, it means that his telescope was produced in or before that year. Our recent investigation made clear that this telescope was of the Schyrlean type, made of four convex lenses giving erect images, with a magnifying power of about four. Analysis of the design, the fabrication method, the surface decoration of the telescope, and the relating historical episodes all suggest that it was not a Western make at all but produced around the southern coastal area of China, or Taiwan, or Nagasaki, by the East Asians. In the 1720s, the optician of Nagasaki, Mori Nizaemon, responding to the order of the Shogun Yoshimune, produced at least several telescopes for astronomical observations, a few of which still exist. The largest one has a tube length of 340 cm with an objective lens diameter of 73 mm, giving the magnifying power of about ten. It is likely that the shogunal astronomers used this telescope for observations of the planetary surfaces.

Around the 1790s, Iwahashi Zenbei of Osaka started production of refractor telescopes on a commercial basis. His telescopes were characterized by special decorative patterns on the tube surface, so that plenty of imitations and fakes with similar decorations appeared at later times. High-quality telescopes by Iwahashi gave the magnifying power of more than 10–20. Because the Iwahashi's family continued to fabricate their telescopes for four generations, they are most commonly seen in museum collections and antique markets. All the telescopic tubes and caps from Yoshinao's to Iwahashi's were produced by the traditional technique called

Ikkan-bari, which utilizes paper and thin wood glued with urushi lacquer. In 1834, the gunsmith, Kunitomo Tobei, succeeded in completing his first Gregorian reflector telescope for the first time in Japan (Yamamoto, 1937). Currently four brass telescopes of nearly the same size (with an inner tube diameter of 62 mm) are identified as his products. Although it is quite unknown how he could polish the bronze primary mirrors without knowledge of Western modern optics and a mirror-grinding machine, Foucault's method of mirror testing has revealed that at least a few of Kunitomo's telescopes possess parabolic surfaces nearly as accurate as those of contemporary Gregorian telescopes. With one of them, Kunitomo made continuous observations of sunspots for more than 1 year, and during that time he independently discovered the penumbra of the sunspot. It is a shame that his excellent engineering could not find any successors, as pioneering achievements like Kunitomo's have often had a similar fate in the history of Japan.

Octants and Sextants

Octants and sextants are certainly worth mentioning in the history of Japanese astronomical instruments. Dutch sailors first brought octants, superb handy navigational and astronomical instruments, into Japan in the 1770s. Because of having no previous information on the principle of an octant and the Vernier subscale inscribed on its arc, both the issues greatly annoyed Japanese astronomers (Nakamura, 2002). Only the practical usage of an octant on the sea had been known since 1782, through a Japanese translation of the Dutch book on octants written by Cornelis Douwes (1749). It was not before 1800–1810 that scholars in Japan began to understand how an octant works and the principle of the Vernier subscale. Since at that time the shogunal government kept a strict seclusion policy and prohibited construction of ships large enough to enable remote voyages, the Japanese had no chance to use octants and sextants in ocean navigation. This motivated some people to apply octants in

Astronomical Instruments in Japan,

Fig. 2 Drawing of Murata's range finder (1852)

measuring angles of distant targets on the ground. Several books explaining how to use octants and sextants in land surveying were written up to the middle of the nineteenth century. One problem with an octant in measuring angles of ground targets was systematic errors due to the parallax caused by a separation between the two mirrors comprising major components of an octant. On the contrary, some land surveyors, like Murata Sajuro, made positive use of the parallactic problem. He introduced, in his book of 1852, a range finder which is a heavily deformed octant having a very wide mirror separation (Fig. 2); Murata's book describes range finders with mirror separations of 1.8, 3.6, and 5.4 m. The left panel of Fig. 2 indicates that this instrument was invented for military purposes to measure the distance of a ship on the sea. After the Meiji Restoration of 1868, modern astronomical instruments imported from Europe soon replaced all the Japanese ones.

Astronomical Instruments in Korea

Young-Ho Hahn

As a country which shares its border with China, ancient Korea also shared many of her neighbor's astronomical achievements. Korea adopted Chinese calendars as a standard and kept identical seasons of the year. But rulers of the Korean peninsula had also tried to establish an independent calendar system, especially during the Chosun dynasty (1392–1910). They attempted to bring out their own almanac at the same level of precision as the Chinese one. Several astronomical projects carried out under the initiative of King Sejong are the best-known examples of such efforts. From 1432 to 1439 a platform, *Ganeuidae*, for the royal observatory was built in the palace and every necessary astronomical instrument was added to it.

Korea has one of the world's oldest observatories, *Chomsungdae*, shown in Fig. 1. It was built in the early seventh century. Another observatory was constructed in the early tenth century and is also extant. Unfortunately only a small number of astronomical instruments and records prior to the fifteenth century have survived. But, as these observatories show, there had been many attempts to read heavenly phenomena even before the Chosun began.

All the astronomical instruments mentioned in this article, although many of them have been lost and are known only through records, are those made during the Chosun period. King Sejong's projects were very important to Korean astronomy. In addition to establishing the first independent calendar, *Chiljeongsan*, various instruments, such as equatorial torquetums [the torquetum or turquet is an instrument designed to take and convert measurements made in three sets of coordinates: horizon, equatorial, and ecliptic], armillary spheres, celestial ► [globes](#), sundials, and auto-striking clepsydras, were introduced. Some of them were made after Chinese models and others were original. The most

Astronomical Instruments in Korea, Fig. 1 World's oldest observatory, *Chomsungdae* in Kyongju

comprehensive description of Sejong's instruments is in Needham's *The Hall of Heavenly Records* (1986).

When Japan invaded Korea in 1592 and burnt down the royal palaces in Seoul, almost every instrument was lost, and Sejong's astronomical instruments were burned. Parts of these were restored after the war according to original designs. While the Court of Chosun was struggling to rebuild after successive raids by Manchurian Qing, Jesuit missionaries in China worked to change the Chinese calendar system to that based on Western astronomy. Officials and scholars of Chosun had to confront unfamiliar Western mathematics and astronomy to catch up with the advanced Chinese calendar. Using projection geometry, they made planar instruments such as astrolabes and sundials for themselves. Finally at the end of the eighteenth century,

Astronomical Instruments in Korea,

Fig. 2 Reconstructed model of simplified instrument *Ganeui* in Yeosu

A

the Korean royal observatory was able to create a pair of unique Western-style sundials.

Each instrument that follows is classified according to its structure and function.

Equatorial Torquetums

An approximately 7 m high, 10 m long and 7 m broad platform of the royal observatory was named *Ganeuida*, because the equatorial torquetum, *Ganeui*, the largest representative of Sejong's observing instruments, was installed on it.

The Korean *Ganeui* was based on Guo Shou-Jing's *Jianyi*, shown in Fig. 2. Guo, of the Chinese Yuan dynasty, invented a new instrument by taking equatorial and meridian rings out and eliminating ecliptic and selenic rings from the traditional armillary sphere. Details of *Jianyi* (literally, simplified instrument) are described and illustrated in Needham's *Science and Civilisation in China*, vol.3 (1959).

Sejong's officials made a wooden prototype and checked the exact polar elevation of Seoul. They completed a bronze-cast *Ganeui* in 1433. Although much simpler in shape than an armillary sphere with multiple-layered rings, the full-scale Simplified Instrument was too large to handle easily. In 1434 King Sejong ordered his

scholars to make a smaller version, and they made two copies of the portable *Soganeui* (Small Simplified Instrument), shown in Fig. 3.

Sejong's astronomers also created a unique observing device, *Ilseongjeongsieui* (Sun-and-Star Time-Determining Instrument). As its name implies, this instrument was both a sundial and stardial. With triple equatorial dial plates, double axially protruded polar-sighting rings, an alidade, and two sighting threads, the direction of the sun and some specified stars near the north pole could be read. This in turn revealed the time of observation. Figure 4 shows the reconstructed model of the round-the-clock time-determining instrument.

Armillary Spheres, Celestial Globes, and Astronomical Clocks

After Guo Shou-Jing's *Jianyi*, armillary spheres in East Asia were based on the Simplified Instrument, not on platforms of observatories. They became the driving mechanism of the indoor astronomical clock. Although the first Chinese astronomical clock dates back to the second century AD, it was at the end of the eleventh century that Su Sung's *Shuiyunyixiangtai* (Water-Powered Sphere and Globe Tower), appeared in China. The inner rings of the armillary sphere and

Astronomical Instruments in Korea, Fig. 3 Reconstructed model of small simplified instrument *Soganeui* in Yeoju

the star-embedded sphere of the celestial globe were rotated by a water wheel in accordance with each heavenly body. The sketch of the clock tower in Fig. 5 is taken from Su Sung's book, and more details of this gigantic clock may be found in Needham's *Heavenly Clockwork* (1986).

China's long tradition of astronomical clocks culminated in Su Sung's work in the Sung dynasty. During the succeeding Yuan period, such water-driven clocks as Guo Shou-Jing's Lantern Clepsydra and Emperor Shun-Ti's Palace Clepsydra were made. But they were not classified as astronomical clocks because they did not have any devices like spheres or ► globes to indicate heavenly motions.

King Sejong revived the East Asian tradition of astronomical clocks in Korea by equipping a

Astronomical Instruments in Korea, Fig. 4 Sun-and-star time-determining instrument *Ilseongjeongsieui* reconstructed

water-operated sphere and globe near his observatory. Except for the layout and size of the instruments, the basic structure of Sejong's clock is thought to be the same as Su Sung's.

In 1438 the artisan Jang Young-Sil made one more water-powered astronomical clock, *Heumgyonggaknu*, close to King Sejong's inner palace. The Clepsydra of the Respectful Veneration Pavilion, although it vanished long ago, is one of the most spectacular astronomical clocks ever made in Korea.

A ball-shaped golden figure moved round the 7 ft. high mountaintop while keeping the same polar distance and directions of rising and setting to the sun for each season. Below the sun image

Astronomical Instruments in Korea, Fig. 5 Su Sung's water-powered sphere and globe tower

stood four jade female gods at the four cardinal points, each with an animal-figured direction god. The ringing of a golden bell in the hand of a god and the turning of the accompanying animal god announced the beginning and middle of the double hours. There was a high platform at the southern foot of the mountain, on which hammers struck their respective instruments to announce the assigned double hour or night watch. On the ground level 12 jade gods surrounded the mountain, paired with each hour god. In addition to the extra platform carrying an inclined vessel, there were paintings of rural scenery during the four seasons and wooden carvings of men, birds, and plants.

This splendid clepsydra was totally destroyed and restored twice over 200 years. Two decades after the abolition of *Heumgyonggaknu*, Yi Min-Cheol made an armillary clock as the

successor of Jang Young-Sil's clockwork in the mid-seventeenth century. The new armillary clock was derived from Sino-Korean astronomical clepsydras, but it had a considerably different appearance. Yi built a cabinet in which water-operated driving mechanisms and a time-announcing apparatus were contained. An armillary sphere, as a part of astronomical clock, was installed on the plinth connected to the box.

Song Yi-Young, in close cooperation with Yi Min-Cheol, made an additional weight-driven armillary clock at the same time in 1669. Instead of Yi's water-powered device he adopted the driving mechanism that had been applied to Western mechanical clocks. Fortunately, as shown in Fig. 6, an improved version of Song's armillary clock has survived and is preserved in the Museum of Korea University, Seoul. Needham devoted one whole chapter of *The Hall of Heavenly Records* (1986) to describing this clock; he wrote that the Song Yi-Young/Yi Min-Cheol clock deserved widespread recognition as a landmark in the history of East Asian horology.

Western astronomy and astronomical instruments began to spread to Korean scholars from the early part of the eighteenth century. Hong Dae-Yong made the last astronomical clock in East Asia. He coupled a mechanical clock directly with the sidereal components of his armillary sphere and attached kinds of differential gears to distinguish solar and lunar motions from sidereal movement.

In 1789 the royal observatory made an equatorial armillary sphere to correct the records of meridian transits. Taking a Westernized, Chinese armillary sphere as a model, Kim Young made Chosun's first observing armillary sphere that could measure heavenly bodies at the accuracy level of 15 s.

Astrolabes

The early Jesuit missionaries introduced astrolabes to China. Books on planispheric or universal astrolabes had been published in Chinese

Astronomical

Instruments in Korea,

Fig. 6 Armillary clock in the Museum of Korea University, Seoul

Astronomical Instruments in Korea, Fig. 7 Korean relics of celestial planisphere (left) and universal astrolabe (right)

during the first quarter of the seventeenth century. However, the actual astrolabes did not arouse as much interest from Chinese scholars as the books introducing those instruments. Thus China did not leave any trace that showed practical uses for Western-style astrolabes except the celestial planisphere, *Pinghunyi*.

More than 100 years later, Korean scholars made all the Western planar instruments for themselves from reading these foreign books. But the planispheric astrolabe was uncommon in Korea too. The plate of the Western astrolabe was replaced with the planispheric star chart in

Pinghunyi, and the rete was revised simply to an arc of horizon on the eastern instrument as shown in Fig. 7. Although several celestial planispheres have been handed down, universal astrolabes are very rare. Moreover, no planispheric astrolabe has survived.

Sundials

Ancient Korea contributed to the diversity of sundials by adding her unique shadow-tracking instruments. Especially during King Sejong's

Astronomical Instruments in Korea, Fig. 8 A scaphe sundial *Angbuilgui*

reign, several distinguished solar devices were invented and equipped. The best-known representative is the scaphe sundial, *Angbuilgui*. This sundial, shown in Fig. 8, has a hemispherical surface of grid lines. Since the end point of the gnomon coincides with the center of the sphere, the shadow of the sharp end is cast to the grid surface always at a right angle and can be read clearly and accurately even at times near sunrise and sunset. The scaphe sundial was used as a main time indicator throughout the Chosun dynasty.

During the eighteenth century a few horizontal sundials were made; they replaced the role of the scaphe sundial in the Court. The new Western-origin sun trackers had the simple appearance of a flat slab, although the construction of the shadow lines was not easily attainable. Once the geometrical essentials to construct foreign sundials became known, the royal observatory preferred to make horizontal instruments rather than the scaphe sundial with its hemispherical surface of shadow lines.

Among these horizontal sundials, *Ganpyongilgui* and *Hongaeilgui* are quite unique. In 1785 these two were carved side by side on the same 1.3 m-long stone table as

shown in Fig. 9. The stone slab with 52 cm width is now preserved in the Royal Relic Exhibition Hall of Deoksu Palace in Seoul.

Ganpyongilgui was based on a Rojas type universal astrolabe and *Hongaeilgui* on a planispheric astrolabe. But the way they were developed was far from simply duplicating the original instruments. The inventor of these sundials, probably one of the high officials of the royal observatory, must have been a master of the principles of planispheric projection to carry out significant modifications for these particular horizontal instruments.

The grid lines of the Rojas type universal astrolabe, *Ganpyonggeui* in Korean, can be obtained by an orthographic projection, whose center of projection is at infinity outside the equinox of the celestial sphere. By analogy, it can be said that *Ganpyongilgui* is a Rojas type sundial since its grid lines were also drawn by orthographic projection. The center of projection of this sundial was located at infinity outside the zenith of Seoul. As the center of projection was moved from infinity outside the equinox to that of local zenith, the straight season lines of the astrolabe *Ganpyonggeui* were transformed to parallel ellipses of the sundial *Ganpyongilgui* because the inclined circles were projected orthographically.

The name of the other sundial was *Hongaeilgui*. Its origin can be traced from the name *Hongaetongheon*, the planispheric astrolabe. The ecliptic on the rete and the lines on the plate of a planispheric astrolabe are obtained by stereographic projection from the south celestial pole. The same rule of projection was followed to get the star chart of a celestial planisphere. Moreover, the season and hour lines of *Hongaeilgui* were also drawn by stereographic projection.

The way to get the grid lines for *Hongaeilgui* is sketched briefly in Fig. 10. Unlike having the center of projection at infinity as in an orthographic projection, the center of the stereographic projection remains on the surface of the celestial sphere. Whenever curves on a sphere are mapped onto a flat surface, there are two characteristic features of the stereographic projection. One is

Astronomical Instruments in Korea, Fig. 9 *Ganpyongilgui* (left) and *Hongaeilgui* (right)

Astronomical Instruments in Korea, Fig. 10 Stereographic projection of *Hongaeilgui*; (a) season lines, and (b) hour lines

the preservation of the circle and the other the rule of conforming. Every circle on the sphere maps onto a plane as a circle by the rule of preserving the circle. And, according to conforming, two circles that intersect at a certain angle will intersect at the same angle on the mapped surface.

The sun is traced for the Korean planispheric sundial, *Hongaeilgui*. The altitudinal and azimuthal data are cast as shadows of the gnomon

onto the surface of the sun tracker. Season and hour lines were constructed as grids on the sundial. By shifting the center of projection to the local zenith, the horizontal coordinates of the sphere were transformed to the polar coordinates. The equatorial coordinates were mapped to the sundial as the bipolar coordinates of the season and hour lines as shown in Fig. 10. The direction of the shadow directly gives an azimuthal coordinate and its length; the altitude

of the sun yields a radial coordinate through a simple transformation:

$$\frac{r}{R} = \tan\left(\frac{90^\circ + \beta}{2}\right) = \frac{1 + \sin \beta}{\cos \beta}$$

$$= \frac{1}{a} + \sqrt{1 + \frac{1}{a^2}}$$

where r is the radial coordinate, R is the radius of the base circle representing horizon, β is the altitude of the sun, and a is the length of the shadow when the height of the gnomon equals unity. With the polar coordinates of the shadow in hand, the point that specifies the current date and hour would be located from the bipolar coordinates.

This Korean horizontal sundial is more of a graphical calculator than a mere time indicator. Most problems concerning the position of the sun throughout a year could be answered straightforwardly without any further calculation. While keeping the geometric characteristics and drawing procedure unchanged, the well-established astrolabe was completely modified by a Korean expert to an extraordinary sundial.

Astronomical Instruments in the Islamic World

David A. King

Frankfurt University, Frankfurt am Main, Germany

Most Islamic observational instruments are lost and known to us only through texts. The state of documentation of the other, smaller Islamic astronomical instruments that do survive leaves much to be desired. Many of the most important instruments are still unpublished, and much that has been written on instruments is on a very amateur level. For these reasons a project has been underway in Frankfurt to catalogue all Islamic instruments (and European ones) to ca. 1550 as well as various historically significant later Islamic pieces.

Also the most important writings on instruments have not yet received the attention they deserve. For example, a hemispherical observational instrument for a fixed latitude was devised by the tenth century astronomer ► [al-Khujandī](#), the leading instrument maker of the early period, and this was modified in the twelfth century to serve all latitudes. There are no surviving examples, and the available manuscripts have yet to be studied. An important work on instruments was compiled in Cairo ca. 1280 by Abū ʿAlī al-Marrākushī – this has yet to be subjected to a detailed analysis. The author collected all of the treatises on instruments known to him and incorporated them into his book. An exciting find of the 1980s was a treatise by the early fourteenth century Cairo astronomer Najm al-Dīn al-Misrī. In this the author described and illustrated over 100 different instrument types, including every kind of instrument known to him as well as those

he invented himself. This treatise is now published with an exhaustive commentary. The same holds for the earliest surviving corpus of texts on the astrolabe, quadrant, and sundials by ► [al-Khwārizmī](#).

Armillary Spheres and Globes

In the eighth century al-Fazārī wrote a treatise on the armillary sphere, called *dhāt al-ḥalaq*, which means “the instrument with the rings.” No early Islamic armillary spheres survive, but several other treatises on it were compiled over the centuries. The earliest treatise in Arabic dealing with the celestial globe, called *dhāt al-kursī* (the instrument with the stand) or simply *al-kura* (sphere), was written by ► [Qusṭā ibn Lūqā](#) in the ninth century. This treatise by Qusṭā, who was one of the most important translators of Greek works into Arabic, remained popular for a millennium. Of the various surviving celestial ► [globes](#), which number over 100, none predates the eleventh century.

The spherical astrolabe, unlike the armillary sphere and the celestial globe, appears to be an Islamic development. Various treatises on it were written from the tenth to the sixteenth century, and only one complete instrument, from the fourteenth, survives. In the ninth century Ḥabash wrote on the spherical astrolabe, the armillary sphere, and the celestial globe, as well as on various kinds of planispheric astrolabes.

Astrolabes

Al-Fazārī also wrote on the use of the astrolabe (Arabic *aṣṭurlāb*). The tenth century bibliographer Ibn al-Nadīm states that al-Fazārī was the first Muslim to make such an instrument – he also informs us that, at that time, the construction of astrolabes was centered in Harran and spread from there. Several early astronomers, including Ḥabash, al-Khwārizmī, and ► [al-Farghānī](#), wrote on the astrolabe, and introduced the features not found on earlier Greek instruments, such as the shadow squares and trigonometric grids on the

backs and the azimuth curves on the plates for different latitudes, as well as the universal plate of horizons. Also extensive tables were compiled in the ninth century to facilitate the construction of astrolabes.

Another important development to the astrolabe occurred in Andalusia in the eleventh century, when al-Zarqāllu devised the single universal plate (*ṣafīḥa*) called *shakkāziyya* and the related plate called *zarqālliyya* with two sets of *shakkāziyya* markings for both equatorial and ecliptic coordinate systems. The latter was fitted with an alidade bearing a movable perpendicular straight edge (transversal). Several treatises on these two instruments exist in both Western and Eastern traditions of later Islamic astronomy – the Europeans knew of them as the *saphea*. Ibn al-Zarqāllu’s contemporary, ‘Alī ibn Khalaf, wrote a treatise on a universal astrolabe that did not need plates for different latitudes. This treatise exists only in Old Spanish in the *Libros del Saber*, and was apparently not known in the Islamic world outside Andalusia. The instrument was further developed in Syria in the early fourteenth century: Ibn al-Sarrāj devised in Aleppo a remarkable astrolabe that can be used universally in five different ways.

The astrolabes made by Muslim craftsmen show a remarkable variety within each of several clearly defined regional schools. We may mention the simple, functional astrolabes of the early Baghdad school – the splendid astrolabe of ► [al-Khujandī](#) of the late tenth century, which started a tradition of zoomorphic ornamentation that continued in the Islamic East and in Europe for several centuries – the very different astrolabes of the Andalusian school in the eleventh century and the progressive schools of Iran in the thirteenth and fourteenth centuries – and the remarkable instruments from Mamluk (thirteenth and fourteenth century) Egypt and Syria. In the early fourteenth century Ibn al-Sarrāj of Aleppo, a school unto himself, produced the most sophisticated astrolabe ever made. After about 1500 the construction of astrolabes continued in the Maghrib, in Iran, and in India until the end of the nineteenth century. Many of these

instruments, especially those from Iran, were beautiful objects of the finest workmanship.

Quadrants

Another category of observational and computational devices to which Muslim astronomers made notable contributions was the quadrant, of which we can distinguish three main varieties. Firstly there is the sine quadrant with an orthogonal grid. This instrument, in a simpler form, had already been described by ► [al-Khwārizmī](#) and was widely used throughout the Islamic period. Some Islamic astrolabes display such a trigonometric grid on the back. The grid can be used together with a thread and movable marker (or the alidade of an astrolabe) to solve all of the standard problems of spherical astronomy for any latitude. Secondly there is the horary quadrant with fixed or movable cursor. This instrument is described already in an anonymous ninth century Iraqi source and was likewise commonly used for centuries (albeit usually without the cursor, which is not essential to the function of the device). A set of arcs of circles inscribed on the quadrant display graphically the solar altitude at the seasonal hours (approximately, according to an Indian formula). Other Islamic quadrants from the ninth century onwards had markings for the equinoctial hours. The instrument can be aligned towards the sun so that the time can be determined from the observed altitude using the grid. Again this kind of marking was often found on the back of astrolabes. Thirdly there is the astrolabic quadrant displaying one-half of the altitude and azimuth circles on an astrolabe plate for a fixed latitude, and a fixed ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The effect of the daily rotation is achieved by a thread and bead attached at the center of the instrument rather than by the movable astrolabe rete. The quadrant with astrolabic markings on one side and a trigonometric grid on the other generally replaced the astrolabe all over the Islamic world (with the notable exceptions of Iran, India, and the Yemen) in the later period of Islamic astronomy.

Sundials

We learn from Islamic tradition that the pious Umayyad Caliph ʿUmar ibn ʿAbd al-ʿAzīz (fl. Damascus, 718) used a sundial to regulate the times of the daytime prayers in terms of the seasonal hours. The earliest sundials described in the Arabic astronomical sources are planar, usually horizontal, but also vertical and polar. The mathematical theory for computing the shadow for the seasonal hours at different times of the year and the corresponding azimuths was available from Indian sources, which seem to have inspired the Islamic tradition more than any of the available Greek works. The treatise on sundial construction by al-Khwārizmī contained extensive tables displaying the polar coordinates of the intersections of the hour lines with the solstitial shadow traces on horizontal sundials for 12 different latitudes. The treatise on sundial theory by Thābit ibn Qurra contains all the necessary mathematical theory for constructing sundials in any plane – likewise impressive from a theoretical point of view is the treatise on gnomonics by his grandson Ibrāhīm.

The earliest surviving Islamic sundial, apparently made in Córdoba about the year 1000 by the Andalusian astronomer Ibn al-ṣaffār, displays the shadow traces of the equinoxes and solstices, and the lines for the seasonal hours as well as for the times of the two daytime prayers. There is a world of difference between this simple, carelessly constructed piece and the magnificent sundial made in the late fourteenth century by Ibn al-Shāṭir, so devised that it can be used to measure time with respect to any of the five daily prayers. In the late period of Islamic astronomy a sundial was to be found in most of the major mosques.

Miscellaneous

Muslim astronomers devised several multi-purpose instruments. Notable examples are the rule (*mīzān*) of al-Fazārī, fitted with a variety of non-uniform scales for various astronomical functions, and the compendium of Ibn al-Shāṭir,

comprising a magnetic compass and qibla-indicator, a universal polar sundial, and an equatorial sundial. Of particular interest is three circular qibla-indicators made in Isfahan ca. 1675 (but invented much earlier) which consists of a cartographic grid with Mecca at the center, so devised that the qibla can be read off the outer scale and the distance from Mecca can be read off the non-uniform scale on the diametrical rule.

There are several Islamic treatises on eclipse computers and planetary equatoria for determining the positions of the planets for a given date. With these the standard problems of planetary astronomy dealt with in *zīj*es are resolved mechanically, without calculation. Treatises on eclipse computers are known from the early tenth century, and ► [al-Bīrūnī](#) in the early eleventh describes such an instrument in detail. A newly discovered manuscript (not yet available for research) contains a treatise by the tenth century Iranian astronomer ► [Abū Ja'far al-Khāzin](#) describing an equatorium called ► [Zīj al-Safā'ī](#) (the Zīj of Plates). The only known example of this instrument, made in the twelfth century, is incomplete: it is in the form of an astrolabe with tables engraved on the *mater* and additional markings for the foundation of an equatorium. Otherwise the only known early Islamic treatises on planetary equatoria are from eleventh century Andalusia. The most interesting aspect of the equatorium described by al-Zarqāllu is the ellipse drawn on the plate for the center of the deferent of Mercury – it seems that he was the first to notice this characteristic of Mercury's deferent. Al-Kāshī, the leading astronomer of early fifteenth century Samarqand, has left us a description of a planetary equatorium with which not only ecliptic longitudes but also latitudes could be determined and eclipses calculated.

Astronomical Monuments in Polynesia and Micronesia

César Esteban

Instituto de Astrofísica de Canarias, La Laguna, Santa Cruz de Tenerife, Spain

The pre-European inhabitants of the Pacific Islands were skillful and frequent interisland navigators. The most accurate directional indicators used by the Polynesian and Micronesian islanders – still used today in several parts of Oceania – were the rising and setting positions of stars (Akerblom, 1968; Gladwin, 1970; Goodenough, 1953; Grimbale, 1931; Lewis, 1994). The measurement of stellar positions and their movement over the celestial sphere was an important task for the ancient seafarers. In fact, astronomy was treated as a branch of navigation by the ancient Tongans (Collocott, 1922), and, as the Jesuit priest Fr. Cantova reported from castaways from Woleai (Caroline Islands) at Guam in 1721, “The only thing they learn are some vague principles of astronomy to which most apply themselves due to its usefulness in navigation” (Lewis, 1994, p. 112). The navigators defined the sailing directions by the use of “star compasses,” which divide the horizon into a number of parts identified by the rising and setting positions of the stars. There is ample evidence of the use of a 32-direction “star compass” by the ancient and contemporary navigators of the Caroline Islands (Goodenough, 1953, pp. 5–24; Gladwin, 1970, pp. 147–165; Lewis, 1994, pp. 102–111). The references for the use of a “star compass” in Polynesia are ancient and scarce. The most

detailed one is by Andía y Varela, who led a Spanish expedition to Tahiti in 1774 (Corney 1913–1919, 2, pp. 284–285; Lewis, 1994, p. 84).

There are few ethnohistoric references about systematic observation of the Sun or Sun worshiping in Polynesia. For example, Behrens, in 1737, says that in the early morning, Easter Island inhabitants “had prostrated themselves towards the rising sun and had kindled some hundreds of fires which probably betokened a morning oblation to their gods” (Behrens, 1908, p. 133). There are some vague indications of solstitial observation in pre-European Pukapuka and New Zealand (Beaglehole & Beaglehole, 1938, p. 349; Makemson, 1941, pp. 85–86) and the more explicit ones are in Hawaii (see Kirch, 2004a, and references therein). However, the most clear evidence of Sun observations is in Mangareva (Gambier Islands), where Buck (1938, pp. 414–415) indicates that “two stones were set up to form sights” to determine the solstices exactly.

There are several ethnological studies about Polynesian names of stars, constellations, and the calendar, the most important compilations being those by Makemson (1941) and Johnson and Mahelona (1975). A new revised work by Johnson, Mahelona, and Ruggles is expected to appear in 2014. In a recent synthesis of historical anthropology, Kirch and Green (2001, pp. 260–276) have reconstructed essential aspects of ancient Polynesian time reckoning and ritual cycle. They describe:

1. An annual seasonal cycle divided in two parts originally based on a wet–dry seasonality and the yam cultivation cycle.
2. A sidereal cycle based on the observation of the heliacal and acronychal rising of the Pleiades (named Mataliki in Proto-Polynesian).
3. An agricultural annual lunar calendar of 13 months.
4. A system of intercalation for keeping the synchronization between the lunar calendar and solar year. This system was based on the observation of Pleiades risings but, in some cases, at least in Mangareva and Hawaii, also on solar observations at solstices.

Astronomical Monuments in Polynesia and Micronesia, Fig. 1 Number histogram of the orientations of the perpendicular to the long side of 26 *ahu* within 500 m of the coast and with long axes skewed by more than 20° to the adjacent shoreline of Easter Island measured by

Liller (2000b). Data are binned in 3° interval. JS, E, and DS indicate the azimuths of the rising sun at June solstice, the equinoxes, and December solstice, respectively. Note the overwhelming tendency of east–west orientations (Diagram adapted from Liller (2000b))

It is surprising that there have been rather few attempts to correlate the ethnographic material about celestial lore and the alignments of the ubiquitous ceremonial stone structures across the whole Pacific area.

There are few archaeoastronomical studies in Polynesia and they are not systematic except for Easter Island and – in recent years – Hawaii. In the case of Micronesia, the situation is even worse. As far as I know, there has been no archaeoastronomical fieldwork on orientations of prehistoric Micronesian stone monuments except the works by Esteban (2007, 2014). In the following, I will review the main results of different research works in the Pacific area. Not all the islands groups are included because an important number of them are lacking any kind of archaeoastronomical study.

Ferdon (1961) made the first report of astronomical alignments in Polynesia as part of the investigations of the Norwegian Archaeological Expedition to Easter Island in 1955–1956. This author proposed that a group of cup-marked boulders (the so-called Sun stones) at the village of Orongo was oriented astronomically; however a reanalysis made by Lee and Liller (1987) has shown that such claims can be discounted. The archaeologist Mulloy (1975) discovered the unusual orientation of one of the scarce inland *moai* platforms (the *moai* are the large imposing Easter Island statues): Huri A Urenga, which faces the point where the Sun rises at the June

solstice. Liller and Duarte (1986) performed an excellent analysis of the orientations located at this monument, reinforcing the astronomical interest of the site and finding other possible astronomical orientations. Mulloy (1961) and Smith (1961) also reported possible solar alignments in other coastal *moai* platforms of Easter Island, such as those of Vinapu 1 and 2 (December solstice sunrise and equinox sunrise, respectively) and Tepeu (December solstice sunrise).

Liller (1989) has made a systematic study of orientations defined by several hundred *ahu* (an *ahu* is a raised platform inside a temple) and *moai* platforms on Easter Island, finding that there is marginal evidence of alignments related to the solstices or equinoxes. He finds a definite trend among coastal *ahu* being oriented parallel to the coast (approximately 90 %), with the sculptures or *moai* facing out to sea. Considering the *ahu* with long sides nonparallel to the shoreline (a sample of 26 *ahu*), there is an overwhelming tendency for these monuments to be oriented in the direction of the equinox rising points and an extra one or two *ahu* aligned in the direction of the solstice rising points (Fig. 1). Regarding the inland platforms, Liller finds there is a weak tendency to have the *moai* look in the direction of the rising of the Sun at the June solstice, and Huri A Urenga stands out as the most remarkable case. More recently, Edwards and Belmonte (2004), considering the outstanding ethnographic importance of Matariki (the Pleiades star cluster see,

e.g., Tilburg, 1994, pp. 100–103) and Tautoru (Orion's Belt) as markers of ceremonies and agricultural activities in the traditional calendar of Easter Island and the absence of solar references or cults, propose that the aforementioned solstitial and equinoctial alignments of the *ahu* platforms could be interpreted as being instead alignments to the Pleiades and Orion's Belt risings or settings. The declination of those asterisms is incidentally very similar to those of the Sun at the June solstice (Pleiades) and to the Sun at the equinoxes (Orion's Belt).

Since the pioneering studies of the Hawaiian stone temples (*heiau*) by Stokes in 1906–1909 (published in 1991: Stokes, 1991), Emory (1924) and Bennett (1931) it has been usually considered that the orientation of the *heiau* was determined by the local topography and environmental considerations, commonly facing the sea or valley. Moreover, as Kirch (2004a) has pointed out, the rich Hawaiian ethnohistory is largely silent about *heiau* orientations. Only the native Hawaiian scholar Malo (1951) indicates that the cardinal directions could have been important for the positioning of the audiences in the *heiau* during the ceremonies. Chauvin (2000) defends the low probability of premeditated solar alignments in the stone temples considering that neither solstices nor equinoxes played any role in the Hawaiian calendar or in religious practices. On the other hand, Kirch (2004a) indicates that the major Hawaiian deities were associated with particular directions and seasonal orientations on the basis of what is known of traditional Hawaiian theology. This assertion suggests that the finding of astronomical alignments in temple platforms may not be disregarded. On the other hand, Ruggles (2001) is also optimistic, at least in the possibility of some symbolic celestial connections in the *heiau* taking into account the large number of names of stars and other celestial objects in the traditional Hawaiian names for places in the landscape. Ethnographical data give evidences of solar observations among the ancient Hawaiians. For instance, Kamakau (1976, pp. 13–14) indicates the existence of persons who observe the stars and a class of priests who advised concerning building and locating

temples who were skilled in reckoning the months of the year and following the Sun movement. This author (1976, p. 14) also describes solar observation from the island of Kauai based on the rising or setting of the Sun over relevant topographic features of the horizon in particular moments of the year.

Rubellite Johnson carried out the first archaeoastronomical studies in Hawaii in the 1980s. Da Silva and Johnson (1982) first suggested a possible “astronomical-directional register” in the *Ahu a 'Umi Heiau*, a platform located on the island of Hawaii, the highest and the farthest inland *heiau* of the Hawaiian archipelago. Johnson (1993) also studied the small island of Kahoolawe, where oral tradition suggested that it had once been a place of important astronomical and navigational activity. Meech and Warther (1996) have made an interpretation of some *hula* or sacred chants of the Hawaiians in terms of astronomical alignments that can be found in the archipelago, specially related to the solstices. However, reassessments based on more precise measurements have shown that the alignments claimed by those authors are not sufficiently precise in most cases (Ruggles, 1999). Moreover, the results obtained by Ruggles seem to indicate an interest in solar zenith passage as much as and perhaps more than in the solstices. In a subsequent paper, Ruggles (2001) presents a systematic study in Kaua'i trying to correlate ritual and sky traditions with the architectural alignments of a large sample of *heiau*, a promising new approach in Polynesia where many traditions are still alive or collected in the rich ethnological legacy. In this last study, Ruggles finds no consistent patterns with regard either to orientation upon topographic features or to orientation upon celestial objects, although some intriguing relationships are found in some particular sites. However, other works have been successful in finding rather clear astronomical orientations in ancient Hawaiian temples. Liller (2000a) has studied the orientations of 32 stone temples in the tiny Necker Island. This island has two relevant particularities: (a) it has an astonishingly large number of temples considering the small size of the island and (b) the island center

Astronomical Monuments in Polynesia and Micronesia, Fig. 2 Number histogram of the orientations of the perpendicular to the back side of 32 *stone temples* of Necker Island (Hawaii Archipelago) measured by Liller (2000a). Data are binned in 5° intervals. JS, E, and DS

indicate the azimuths of the rising sun at June solstice, the equinoxes, and December solstice, respectively. Note that the *temples* show two preferred orientations: one east–west and the other around the December solstice sunrise (Diagram adapted from Liller (2000a))

Astronomical Monuments in Polynesia and Micronesia, Fig. 3 Number histogram of the orientations of 23 *heiau* at Kahikinui (Maui Island, Hawaii Archipelago) measured by Kirch (2004a). Data are binned in 10° intervals. The position of the cardinal points is indicated by

letters. The data show three clear concentrations: one facing the east, another facing east–north–east, and a third one facing north, Kirch (2004a) believes these orientations were deliberate and likely related to a particular god of the Hawaiian pantheon

is located almost exactly at the latitude of the Tropic of Cancer in the year AD 1000. This last particularity implies that the ancient inhabitants of Necker would have realized that the Sun was directly at their zenith at midday of the June solstice. In fact, Liller has found that 9 of the 32 temples of Necker are aligned with the setting June solstice and/or the rising December solstice (Fig. 2). Finally, Kirch (2004a) has performed an analysis of the orientations of a sample of 23 *heiau* of Kahikinui (Maui Island). This author has found that temple foundations tended to have three preferred orientations: east, east–north–east, and north (Fig. 3). Kirch has correlated these results with ethnohistoric and ethnographic data proposing that:

1. The east orientations may be associated with god Kane, because this deity was associated with the Sun and the east direction.
2. The east–north–east cluster of orientations may be related to either the summer solstice sunrise or the rising of the Pleiades. In fact the acronychal rising of this asterism determined the onset of the Makahiki season and the new year; this group of temples may be dedicated to the god Lono, who was linked to the annual rising of the Pleiades.
3. The temples oriented to the north face the summit of the high mountain Haleakala (“House of the Sun”) and may be dedicated to Ku, a deity linked to high mountains, to the sky, and to forest.

Archaeoastronomical studies in islands of Eastern Polynesia, apart from the aforementioned ones for Easter Island and the Hawaiian archipelago, are very scarce. Liller (1993) presents an analysis of orientation data (obtained from direct measurements by the author and from good quality topographical maps) of over 50 ceremonial stone platforms in various archipelagos of Polynesia (Society Islands, Hawaiian Islands, Rarotonga, and the Trilithon of Tonga) finding no clear astronomical trends except perhaps in some isolated cases. In a subsequent paper, Liller (2000b) gives an excellent review of archaeoastronomical fieldwork carried out in Polynesia and presents some new results based on the reanalysis of large sets of published plans from the literature and some other new data obtained by the author. Concerning the archipelagos of Eastern Polynesia, Liller presents histograms of orientations of temples belonging to the Tuamotus (52 temples) and the Society Islands (105 temples) as well as some preliminary and sparse data of Mangareva, the Cook Islands, and the Austral Islands. The general conclusion of that paper is that the orientation of the Polynesian ceremonial platforms was controlled by the physical situation. Most of the monuments are located on the shore and lie parallel or perpendicular to the immediate shoreline. Astronomical alignments are present only in some isolated cases. The remarkable *mara'e*. (*Mara'e*, also spelled *mala'e* or *maa'e*, are stone or coral slab temples) Tapu-tapu-a-tea, possibly one of the most important in all Polynesia, located on Raiatea (Society Islands) has its long inland-facing wall oriented to an azimuth of $6.^\circ 3'$. Liller (2000b) suggests that the perpendicular to the wall may be oriented to the rising point of the southern portion of the constellation of Orion: perhaps Orion's Belt or Rigel. Other important *marae* of the Society Islands, such as those of Tainu'u (Rai'atea), Mataireia-rahi and Anini (Huahine), Marotetina (Borabora), Mahaiatea (Tahiti), and Tetii (Mo'orea), are also oriented to within a few degrees of that of Tapu-tapu-a-tea (Liller, 2000b). This finding could be relevant in the context of the ethnohistorical accounts of Henry (1928, p. 363) who writes the following concerning the birth of

heavenly bodies in ancient Tahitian tradition: "the chiefs of the skies... were royal personages... from the period of darkness, and they each had a star. They bore the names of those stars, and those names have been perpetuated in their temples in this world." This account suggests that the finding of stellar alignments in the *mara'e* cannot be considered strange (Kelley & Milone, 2005, p. 347). On the other hand, unpublished archaeological surveys of *mara'e* in the Faaroa Valley (Raiatea) and Mataireia Hill (Huahine) carried out by Edmundo Edwards indicate that a fraction between 20 % and 30 % of the monuments show solstice orientations, although Liller (2000b) considers that Edward's results, at least for Huahine, are only circumstantial.

As in the case of the aforementioned Necker Island in the Northern Hemisphere, there are several islands of Eastern Polynesia located close to – in this case – the Tropic of Capricorn. Tubuai (Austral) was located only 23 km north of this tropic in AD 1000 (Liller, 2000a). Vérin (1969) found that four out of six *mara'e* reported on this island show alignment with the December solstice sunset. However, Edwards (2003) indicates that those presumed orientations could be only accidental considering that the nearby shoreline has precisely the same orientation. This last author reports a survey of 92 *mara'e* on Raivavae (Austral Islands), an island also very close to the Tropic of Capricorn, finding that about 14 % of the monuments are astronomically oriented. In particular, the large *mara'e* Unuaru (whose walls are not parallel to the shoreline) as well as other *mara'e* of Raivavae are oriented very close to the true north.

The Mangareva Islands (also known as Gambier Islands) are the only case in Polynesia where there is unequivocal ethnohistoric evidence for systematic solar observations. The account of the priest Honoré Laval provides a description of traditional Mangarevan time reckoning and the methods of solar observations at solstices and the places where they were performed (Laval, 1938, pp. 213–215). Peter Buck (1938) gives another detailed ethnographic account about these activities. Here are some relevant astronomical information (see Kirch, 2004b):

1. Solstice observations were used to keep the lunations in sequence with the solar year and to divide the year into two seasons.
2. The locations for solstitial observations are given. The observatory at Atituiti, named Te Rua Ra (the pit of the Sun), is said to be the “most favorable position” for this purpose.
3. In at least one site, upright stones are used to mark the rising Sun at December solstice, and the backsight was a big flat stone.
4. The observation of solar risings and settings on distant topographic markers was used to achieve precision.
5. The movement of a shadow cast by a certain mountain was also used as a solstitial marker.

Kirch (2004b) has rediscovered the precise site of the Atituiti observatory, finding an uncommon platform oriented along the cardinal directions and the central flat boulder where observations were performed. That author has been able to confirm the most important aspects of the ethnohistoric records. For example, the position of the December solstice sunset coincides with the western edge of the high cliff Ana Tetea (the burial place of two renowned high chiefs of Mangareva) on Agakautai Island; the shadow of Auorotini (Mount Duff) is also cast onto the central flat boulder during the June solstice.

In recent years, the Centre d'Investigation en Ethnoastronomie Locale (CIEL) of Tahiti led by L. Cruchet is carrying out ethno- and archaeoastronomical studies in the area of East Polynesia. In his last work, Cruchet (2013) presents results for a number of *mara'e* and archer platforms in the Society Islands. He proposes that they are oriented to the rising and setting of certain important stars in Tahitian mythology (the so-called pillar stars) and that these relationships can be explained in the light of linguistic and ethnographic data and even attending to their relation with the traditional landscape. Although, in my opinion, these studies have certain methodological deficiencies, the importance of some stellar alignments seems rather plausible.

In the Kingdom of Tonga, we have a remarkable and unique monument in Polynesia: the Ha'amonga a Maui (Burden of Maui) trilithon

which according to tradition, was built in AD 1200 (see Fig. 4). (A trilithon is a structure consisting of two large vertical stones supporting a third stone set horizontally across the top) In 1967, the current monarch, King Taufa'ahau Tupou IV, discovered that the lintel is aligned along the sunrise at December solstice; this was later confirmed by Liller (1993) and Esteban (2002–2003). According to Collocott (1922), “the Tongan year is said to have begun at about the same time as the Christian year” and this fact would indicate a possible calendrical importance of the December solstice. As has been commented before, Makemson (1941) and other authors state that in most of the Polynesian archipelagos (including Tonga), the new year began in late November or early December with the first Moon after the acronychal rising of the Pleiades. These dates are not far off but obviously do not coincide with the December solstice. In any case, as Esteban (2002–2003) has suggested, the solstitial orientation of the trilithon may be accidental because its axis is roughly parallel to other related archaeological structures and to the nearby shoreline. Some controversy was raised by the presence of an enigmatic zigzag figure carved into the top of the lintel of the trilithon whose axes point roughly to the two rising solstice directions. However, Dhyne (1994) argues that there are reasons to believe that the marks were made relatively recently.

The most common archaeological features of Tonga are round or rectangular mounds of earth with considerable size range. These mounds can be house platforms, burial mounds, *esi* mounds (resting places for members of the chief's family), and mounds for pigeon snaring (McKern, 1929). The *esi* and pigeon mounds are usually situated upon natural rises that command a splendid view of the surrounding countryside. The anthropologist Wragge (see Liller, 2000b; McKern, 1929, p. 17) reported that the *esi* platform called Makahokovalu in Uiha Island (Ha'apai group) was a religious site connected with ancient Sun worshipping. However, McKern (1929, p. 17) and Gifford (1924, p. 68) failed to find any archaeological or ethnological evidence of Sun worship in the island.

A

Astronomical Monuments in Polynesia and Micronesia, Fig. 4 *Left:* The Ha'amonga a Maui trilithon seen from the south (Heketa, Tongatapu Island, Kingdom of Tonga). This is a unique monument in Polynesia that stands about 5 m tall. *Right:* View of the eastern horizon as seen from the lintel of the trilithon. The position of the rising points of the Sun at solstices and equinoxes has been

cleared of vegetation by the Tongan authorities. The lintel is aligned approximately along the December solstice. The current Tongan monarch, King Taufa'ahau Tupou IV, discovered this alignment (Images taken from Esteban (2002–2003). Reproduced with permission of University of Texas Press)

Liller (2000b) reports that in McKern's plan of Makahokovalu, the long axis is oriented at an azimuth of 2° (perpendicular 92°), suggesting some solar relation, but this is also the orientation of the nearby shoreline. Esteban (2002–2003) has estimated the approximate orientation of the ramps of the mounds from the plans published by McKern finding no clear trends.

Since the burial mounds of Tongan commoners are just earth mounds, the sites relating to the chief and royal family have stone facing and are often loosely called *langi*. The *langi* are large rectangular monuments with stone slab retaining walls, generally consisting of a number of terraces in the manner of truncated pyramids. One of Collocott's (1922) informants suggested a connection between the skies and the great burials at Mu'a (Tongatapu Island) and elsewhere, and it is worthy of note that the sky and vault are called by the same name: *langi*. In a detailed study of the largest collection of *langi* at Mu'a, Esteban (2002–2003) finds that the general disposition of the tombs is parallel to the shoreline, although much less probable stellar orientations related to sailing directions are also discussed by that author.

Bellwood (1978) reports that Samoan ethnographic records indicate the existence of open spaces for ceremonies (*mala'e*) as well as god houses. Scattered among Samoan settlements

are the so-called star mounds. They are large, raised platforms with several rounded projections extending from the central area and built with a loose rubble of basaltic stones. The interpretation of star mounds has been controversial. Modern informants tend to view them as pigeon-snaring mounds. No evidence of use for habitation or burial was found. The mounds were perhaps also used for religious purposes, as some ethnological references have pointed out (Davidson, 1979), and also for some divination rituals, as it is indicated in the information panels of the Tia Seu Lupe (literally “earthen mound to catch pigeons”) star mound in Tutuila Island (American Samoa). Esteban (2002–2003) considers it impossible to define useful alignments in these kinds of mounds taking into account their common irregular shape and large number of rounded irregular projections.

The island of Sava'i (Independent Samoa) has what is quite probably the largest surviving prehistoric monument in Polynesia, the Pulemelei stone mound. It is a huge flat-topped and roughly rectangular structure that covers 60 by 50 m at the base and is 12 m high. There are slightly sunken ramps to the top on the eastern and western slopes. The monument was built between 1100 and 1300 AD. There are several oral traditions about its purpose. Some tell that the mound was used to catch

pigeons, while others say it was the residence of former chiefs of the island. Moreover, no few local traditions consider Pulemelei as the residence of gods and spirits. In any case, the archaeological investigations point out its ceremonial character (Martinsson-Wallin, Wallin, & Clark, 2007). This huge monument is part of a large complex of more or less contemporary structures as smaller mounds and traditional footpaths. It is located within a coconut plantation and almost completely covered with vegetation, making it very difficult to make accurate measurements of the orientation of the structure or the horizon without an extensive clearing of vegetation. This took place during the 2002–2004 excavations led by Swedish and Australian archaeologists (see Martinsson-Wallin et al., 2007). Talbot and Swaney (1998, p. 141) and Esteban (2002–2003) indicated that the sides of Pulemelei were oriented approximately along to the cardinal axes, which can be graphically confirmed on the detailed plans of the archaeological site published by Martinsson-Wallin et al. (2007, Fig. 3a) and after correcting for magnetic declination. Clarke and De Biran (2007) report that several of the other large mounds of Samoa also show their major axes oriented along the east–west line, as does the stone platform known as Kine He’e in the relatively nearby island of Rotuma (Fiji), culturally related to Samoa.

The largest island of the Republic of Palau (in Micronesia) is Babeldaob. From the astronomical point of view, the most interesting prehistoric remains known in Palau are the unique sculpted stone faces at Melekeok, on the eastern coast of Babeldaob. They are nine stones ranging from 1 to 2.5 m in height and arranged very precisely in two rows parallel to the nearby shoreline. All the surviving stones are facing the sea. Morgan (1988, pp. 14–15) collected the following legend concerning the origin of these stones: Odalmelech, the god of Ngermelech Village in Melekeok, “and his councilmen set out to lay a huge stone work over the village ground. That night, they started bringing in huge reef stones for the project, but the work was only partially completed when dawn approached. Odalmelech, seeing that his cohorts could not accomplish the project before daylight, called his crew together

and told them of the shame of being caught working in the morning sun. So he ordered his crew to carve all their faces on the monoliths and place them to eternally face the rising sun.” This story indicates the possible astronomical motivation of the site. Esteban (2002–2003) finds that the orientation of the faces may be close to the June solstice rising based on the site plan published by Morgan (1988, p. 13). Direct measurements and additional ethnographic data on the site are necessary to check this suggestive finding.

Nan Madol, in Pohnpei Island (Federated States of Micronesia), is the largest archaeological site in Micronesia and perhaps of all the Pacific Islands. It consists of 92 human-made rectangular islets separated by many waterways. The islets are generally surrounded by retaining walls of long, naturally prismatic basalt which are often built up over foundations of immense basalt boulders. The site was constructed on a reef located in the southeast side of Pohnpei which is called Sounahleng or “Reef of Heaven.”

Esteban (2007, 2014) has analyzed the orientations of several mortuary enclosures of the monumental megalithic city of Nan Madol, finding that the most relevant one, Nan Douwas – the tomb of the former rulers of Pohnpei, located at the easternmost edge of the city – is rather closely oriented with respect to the cardinal points. Towards the eastern horizon, Nan Douwas is facing a narrow channel between two nearby small islands, Nahkapw and Pweliko. Sunrise at the equinoxes or the midpoint in time between solstices occurs just on the north tip of Nahkapw. Some legends tell that the islet of Pweliko – to where Nan Douwas is oriented – is a sacred area, a transit place for the souls of the dead on their way to the final judgment (see Esteban, 2014 and references therein). According to Eastlick (1995), the division between the dry and wet seasons in the traditional Pohnpeian calendar occurs in March and September, approximately at the time of equinoxes. All these facts suggest that the location and orientation of Nan Douwas were carefully planned and that this huge enclosure had a rich ritual, funerary, and perhaps even calendrical symbolism. Another possible astronomical marker on the eastern horizon seen

Astronomical Monuments in Polynesia and Micronesia, Fig. 5 Map of the southeast edge of Pohnpei including Temwen Island, Nan Madol area, and several small reef islands (Na, Pweliko, Nahkapw, and others, map adapted from Morgan, 1988, p. 60; courtesy of the author and the University of Texas Press). The location of the two largest funerary enclosures, Nan Douwas and Karian, is also indicated. The continuous and long-dashed

blue arrows indicate relevant astronomical orientations defined for Nan Douwas and Karian, respectively. The short-dashed arrow indicates the orientation of the perpendicular to the long axis of the outer wall of Nan Madol, which represents the dominant orientation of the southwest part of the city and coincides with the rising point of the Southern Cross (Figure taken from Esteban (2014))

from Nan Douwas is the northern tip of the island of Na, which coincides with the point where the sun rises in the June solstice. An alternative astronomical interpretation also formulated by Esteban (2007, 2014) for the orientations found in Nan Douwas is based on the rising of stars or asterisms at the time of the construction of Nan Madol (about 1200 d. C.). The monument is pointing approximately to the area of the horizon where the stars of Orion's Belt rise. This was an important asterism around the Pacific and one of the directional points of the sidereal compass used by the traditional Micronesian navigators. On the other hand, the northern tip of the island of Na could be related to the rising point of the Pleiades, the most important constellation for the Pohnpeians. Like elsewhere in the Pacific, the heliacal rising of this group of stars has a relevant calendrical significance (Fig. 5).

Astronomy

Roger B. Culver

Astronomy, the study of celestial objects, is a universally human endeavor whose roots lie deeply buried in prehistory. For the sky-watcher devoid of optical aid, the heavens can be thought of as a sort of earth-centered celestial sphere on to which have been sprinkled hundreds of tiny points of light we have called the stars. Half of this inverted bowl of blackness is almost completely dominated by the dazzling presence of the sun, the most prominent and important of the celestial objects. Such is the sun's brilliance that any attempt to view this object directly is to risk serious eye damage or even total blindness. As a result of the earth's spinning motion or rotation, an observer at a given location on the earth sees a sky that alternates between a daytime sky dominated by the sun and a nighttime sky characterized by its absence. As the earth turns on its axis, the sun appears to rise up from a given observer's eastern horizon, pass through a "high noon point" or maximum angle above the horizon, and then descend toward the western horizon. Approximately one half an earth rotation later, the sun once more rises to repeat the

cycle. This rising and falling effect is not limited to the sun. As the earth rotates relative to all celestial objects, they too appear to go through the rising and falling diurnal motions of the sun. Since the rate of the earth's rotation is very nearly constant, this diurnal motion of the sun and stars has long been employed as an important and reliable way of measuring time. The earth's rotation also creates the illusion that the stars of the celestial sphere seem to revolve about two imaginary points located exactly opposite each other. One, the south celestial pole, is visible only from the southern hemisphere of the earth, while the other, the north celestial pole, is visible only from the northern hemisphere. The earth's long-term precessional motion carries the locations of these celestial poles along a 47° diameter circular path among the stars once every 26,000 years. From time to time, a relatively bright star can be found near the position of one of the celestial poles for a few centuries. Such is the case at present for the north celestial pole, which is currently located near the fairly bright star Polaris, the Pole Star.

In addition to its daily rising and setting, the sun also appears to travel along a great circle on the celestial sphere, which is called the ecliptic. This latter movement is the direct result of the earth's orbital motion about the sun. As the earth arcs along in its orbital path, the apparent position of the sun relative to the more distant background stars appears to change. For an observer on the earth, the sun thus seems to creep gradually from west to east among the stars, completing an entire 360° journey around the ecliptic in exactly the same 1 year time interval it takes the earth to complete one orbital revolution about the sun. The background stars hence appear to be gradually overtaken in the western sky by the sun as it moves eastward along the ecliptic, engulfed by the solar glare for a month or so, and then reemerge in the predawn sky as the sun leaves them behind in its ongoing easterly movement. The overall result of this annual movement of the sun is a seasonal parade of the heavens in which different stars are visible at different times of the night at different times of the year.

The earth's axis of rotation is also found to be tilted at an angle of $23\frac{1}{2}^\circ$ off the vertical to the earth's orbital plane. As the earth orbits the sun, this tilt causes the sun to shine alternately more directly on the northern hemisphere and less on the southern hemisphere and then vice versa over the span of a simple year. This effect is observable as a yearly variation of the sun's highest altitude above the horizon at a given location, and as a change in the time that the sun spends above the horizon. Thus when the sun is shining most directly on the northern hemisphere at the time of the summer solstice, the sun's diurnal motion in the northern hemisphere is characterized by long days and short nights, and in the southern hemisphere by short days and long nights. Half an orbital revolution or 6 months later at the time of the winter solstice, when the sun is shining more directly on the southern hemisphere, the lengths of night and day are reversed. Halfway between these extremes the sun shines directly down on the earth's equator twice each year. On these dates, the lengths of the days and nights all over the earth are equal, except at the poles, and hence these dates are said to be the equinoxes. It is this combination of the tilt of the earth's axis of rotation and the earth's orbital motion that gives rise to our cycle of seasons here on the earth.

Firmly entrenched in second place in the brightness hierarchy of celestial objects is the moon. Although not as important as the sun, the moon, none the less, exerts several significant influences on the earth, most notably as the chief agent by which tides are produced in the world's oceans. The reflected sunlight we receive from the moon is over one million times fainter than that emanating from the sun, and as a result, the moon can be readily viewed against the backdrop of the stars of the night sky. As the moon orbits the earth in space, it appears to traverse a great circle about the celestial sphere in a fashion not unlike the annual motion displayed by the sun. There are however some important differences between the lunar motion and that of the sun. The moon swings along an apparent path that is tilted at an angle of about 5° to the ecliptic and takes one-twelfth of the sun's time to make a

single journey about the celestial sphere. The moon thus moves at an average rate of about half a degree per hour relative to the background stars, an angular speed easily detectable over the course of a single night by a naked eye observer.

Although the moon's half degree angular diameter is almost exactly the same as that of the sun, the diminished brightness of the moon permits us to look directly upon its face without fear or danger. As a result, the moon presents a number of most interesting and fascinating phenomena to the naked eye observer. Perhaps the most familiar of these is the set of seeming shape changes or phases exhibited by the moon as it journeys about the celestial sphere. These phases arise from the fact that as the moon orbits the earth, the half of the moon's spherical surface which faces the sun, and is hence illuminated by the sun's light, is viewed at different angles by an observer situated on the earth. When the moon is very nearly lined up between the earth and the sun, almost all of the moon's sunlit hemisphere faces away from the earth, and all we see of the moon is a very thin crescent of light. As the moon moves toward progressively larger angular distances from the sun, the thickness of the crescent grows or waxes until the angle between the moon and the sun as seen from the earth is 90° . At this point we see exactly one half of the moon's sunlit surface and the moon appears to have a semicircular or "quarter-moon" shape. As the sun-moon angular separation increases past 90° , the moon takes on a bulging or gibbous shape whose thickness continues to grow until the moon is very nearly opposite the sun in the sky. When this configuration occurs, the entire sunlit hemisphere of the moon faces the earth, and the now circular-shaped moon is said to be a "full" moon. After passing through the full phase, the moon's shape changes now proceed in reverse order, successively passing through waning gibbous phases, a second or last quarter phase, and finally a waning crescent phase as the angle between the moon and the sun decreases from 180° to nearly zero. The waning crescent moon eventually slides into the predawn solar glare for a few days and then reemerges as a silvery crescent-shaped "new" moon in the postsunset twilight.

The moon is also unique among celestial objects in that it is the only one for which surface detail can be easily viewed with the unaided human eye. This detail manifests itself in the form of the dark areas on the moon's disk which are called maria or seas and the light areas called continents. This terminology dates back to the Western European Renaissance observers of the moon who imagined the lunar surface to be divided between bright land and dark waters.

In addition to the sun and moon, human beings have recognized since prehistoric times that five other naked eye objects also move about the sky relative to the back-ground stars. These star-like wanderers are called planets, and historically have enjoyed the appellations of the gods and goddesses of ancient Greek and Roman mythology. The five so-called naked eye planets have been named, in order of their increasing distance from the Sun, Mercury, Venus, Mars, Jupiter, and Saturn. A sixth planet, Uranus, possesses a brightness which is just at the limit of naked eye visibility, but the planetary nature of this object does not seem to have been recognized until the English astronomer William Herschel accidentally stumbled upon it in 1781.

Two of the planets, Mercury and Venus, have orbits about the sun which are interior to that of the earth. As a result of this orbital geometry and the sun's gravitationally induced faster orbital speeds, these planets exhibit a marked pattern in their appearances in the earth's sky. In a typical cycle, the planet is first visible as an evening "star" in the west after sunset, then appears to move out to a maximum angle of greatest elongation away from the sun before retreating back into the sun's light. After several days or weeks, the planet reemerges from the solar glare, but this time as a morning "star" in the predawn sky. The planet once more moves out to an angle of greatest elongation and then drops back into the solar light. The swiftly moving planet Mercury goes through a complete cycle of appearances or synodic period in about 4 months, while Venus, whose orbital speed is more closely matched to that of the earth, takes a year and a half for its cycle of appearances. Typically Mercury's appearances as a morning or evening star last

about 3 weeks, while those of Venus extend over several months at a time.

Visually, the planet Mercury appears in the sky as a sparkling object having a somewhat reddish-orange tint. Its apparent brightness is actually comparable to the brightest stars, but because it is almost always observed in twilight, it is usually not as impressive an object as it otherwise might be. The most spectacular of the naked eye planets and the third brightest object in the sky behind only the sun and moon is the planet Venus. The orbital path of Venus can carry it out to an angle of greatest elongation as large as 47° , or about twice that exhibited by the planet Mercury. Thus it is possible to observe this splendid object for as long as 4 h after sunset or before sunrise. At its greatest brilliancy, the soft white light of Venus has even been observed to cast very faint shadows as it gleams in the darkness of the predawn or postsunset night sky.

The three remaining naked eye planets Mars, Jupiter, and Saturn, move in vast orbits about the sun which are exterior to the orbit of the earth. As a result, these planets appear most of the time to move about the celestial sphere in a fashion similar to the west to east movement exhibited by the sun and moon. The times required for each of these planets to make a complete cycle about the celestial sphere, however, are far longer than those for the sun and moon. Mars, for example, completes a single journey around the celestial sphere in just under 2 years, while Jupiter and Saturn require nearly 12 and 30 years, respectively, to complete similar journeys. As the faster moving earth catches up to and passes one of these exterior planets, the planet exhibits an illusionary phenomenon in the earth's sky called retrograde motion in which the given planet seems to stop its normal west to east motion among the stars, moves "backward" or east to west for several months, stops again, and then resumes its direct or west to east movement. In the midst of its retrograde motion, a given planet will appear to be opposite the sun's position in the celestial sphere as seen from earth. When such a configuration occurs, the planet is said to be "in opposition to the sun," or more simply, "at opposition." At the time of a given planet's opposition,

the earth makes its closest approach to the planet, and as a result, the planet shines more brightly than at any other time. Moreover, at opposition the planet rises at sunset, sets at sunrise, and is thus visible throughout the night.

Visually, the planet Mars is perhaps the most remarkable of the exterior planets owing to its distinctly reddish hue. At times of closest approach to the earth, the apparent brightness of this ruddy world is exceeded only by that of the sun, Moon, and Venus. When Mars is not at a close opposition, the fourth brightest object in the sky is the yellowish-white planet Jupiter which shines some ten times more brightly than the average of the brightest of the background stars. The golden-colored planet Saturn is the most distant of the naked eye planets from both the earth and the sun, and thus exhibits a reduced apparent brightness which is comparable to the average of the brightest background stars.

While the paths of the planets about the celestial sphere are not coincident with the ecliptic, they are, none the less, nearly coplanar with it. As a result, the sun, moon, and five naked eye planets move about the celestial sphere in a relatively narrow band of sky centered on the ecliptic which is called the zodiac. Because the sun, moon, and planets move along the zodiac at differing rates, it is possible for objects in the sky to appear to pass close to other objects along the zodiac. When such a passage occurs, the resulting configuration of the two objects is said to be a conjunction. Conjunctions can occur among the sun, moon, and planets, as well as between these moving objects and the bright stationary stars which are to be found along the zodiac. From time to time conjunctions can involve three or more objects, and on rare occasions a conjunction can be so close that the two objects cannot be seen as separate with the unaided eye.

In addition to the imaginary band of planetary paths that is the zodiac, there exists a quite real band of diffuse light, called the Milky Way, which is stationary relative to the stars and girds the celestial sphere like a gigantic faintly glowing heavenly belt. The Milky Way is the naked eye manifestation of the vast galactic system of gas, dust, and stars in which our sun is located.

The Milky Way Galaxy, as this system is called, is in the shape of a huge, flat pinwheel which has a substantial bulge at its center. Our sun is situated about two-thirds of the way toward the outer edge of this system, and as a result, our view of the summertime Milky Way in the northern hemisphere is the more prominent one, since at this time we are looking toward the direction in which most of our galaxy is located. On the other hand, in the northern hemisphere winter, our view is now directed away from the galactic center toward the less prominent regions of the galaxy, with the visual result that the wintertime Milky Way is much fainter than its summertime counterpart.

Off the plane of the Milky Way, there exist approximately a dozen or so lesser diffuse objects which are visible to the naked eye and are also set in fixed positions among the stars. Modern telescopic observations reveal that these “fuzzy patches of light” are in reality quite a diverse lot, including clouds of glowing gas, star clusters, and even other galaxies well outside of our Milky Way.

From time to time transitory apparitions and events occur in the sky which can be as awesome as they are spectacular. One such event is a total eclipse of the sun. When the moon passes directly between the earth and the sun, a moving shadow of the moon about 240 km wide is cast upon the surface of the earth. An observer located in the shadow’s path will see the sun’s disk gradually covered by the dark lunar disk until the sun’s light is almost completely blotted out. During this “total” phase of the eclipse, only the light from the sun’s outermost atmospheric layers is visible and a darkness comparable to a full moon night descends on the land for a time period ranging from a few seconds to as long as 7 min. Finally the moon moves out of its direct alignment between the earth and the sun, and the sun reemerges to its full disk and full brightness.

The sun, earth, and moon can also align in such a way that the moon passes into the earth’s shadow, thereby producing a total eclipse of the moon. When such an event occurs, an observer on the earth sees a full moon gradually enter the curved shadow of the earth. When the moon is

totally immersed in the earth’s shadow, it can take on a variety of ruddy hues ranging from an almost totally darkened red to a bright coppery shade of red-orange. This illumination even at the total phase of a lunar eclipse is caused by sunlight being refracted on to the moon’s surface by the earth’s atmosphere. The variety of colorations exhibited during various lunar eclipses is thus the direct result of the weather conditions in the earth’s atmosphere, especially the degree of cloud cover at key locations around the earth. Typically the eclipsed moon spends an hour or so in the total phase before reemerging from the earth’s shadow and regaining its full moon brilliance.

Every few years or so the night sky is visited by a strange apparition, a diffuse “long-haired” star-like object called a comet. Comets are known to be collections of ices, dust grains, rocks, and frozen gases which wheel about the sun in huge elongated orbits which alternately carry them from relative proximity to the sun out to the most distant parts of the solar system, thousands of earth-sun distances away. As a comet approaches the sun, the sun’s radiant energy causes the ices and frozen gases to evaporate into a glowing coma which surrounds the dust and rocks at the comet’s nucleus. As this diffuse, star-like object draws ever closer to the sun, the solar proton wind and radiation pressure drive material out of the diffuse head into a long, streaming tail which can extend over millions of miles of space. For several weeks, like a cosmic messenger, a comet will approach the sun, blossom with a flowing tail, and then fade into the cold blackness that is the periphery of the solar system.

The debris left behind by both these interlopers as well as from the formation process of the solar system permeates the interplanetary medium. As the earth sweeps along its orbit, it is constantly bombarded by objects ranging in size from tiny grains of dust up to small asteroids several kilometers in diameter. Fortunately collisions with the latter are extraordinarily rare! When a given interplanetary particle, called a meteoroid, strikes the earth, it does so at speeds as high as 50 km s^{-1} . At such speeds, friction

with the earth's atmosphere causes the object to heat up quickly and glow brilliantly as it falls toward the earth. An observer at the earth's surface sees this event as a "falling star" or "shooting star." Most of the time, such objects disintegrate in the upper layers of the earth's atmosphere, but occasionally a meteoroid is able to traverse the earth's atmosphere and strike the earth's surface. Such an object is then referred to as a meteorite.

Occasionally the earth passes through a large stream of meteoric debris left behind by a comet. Under these conditions, large numbers of meteors can be seen in the form of a meteor "shower." During a typical meteor shower, one can see anywhere from 15 to 60 meteors per hour above the normal sporadic or background meteor counts of about six meteors per hour. About three or four times per century the earth strikes a particularly large and dense aggregate of meteoroids. Under these circumstances, thousands of meteors per hour flash across the heavens in a display of celestial fireworks which is unmatched anywhere else in the natural world.

From time to time in the remote recesses of interstellar space a star will end its life in a spectacular event called a supernova explosion. For a few days the energy output of this dying object rivals that of all the stars in an entire galaxy. If a supernova detonation occurs at a distance sufficiently close to the earth, the observed result is the transitory appearance of a "new" star in the terrestrial night sky. For time periods ranging from a few days to several months, the star shines at or near its maximum brightness before fading back into naked eye invisibility. One of the more notable of these objects was observed in the year AD 1054. At its maximum brightness, the supernova of 1054 was nearly three times brighter than the planet Venus and could be readily seen in broad daylight. The remains of this stellar blast can be telescopically viewed today as the tattered and twisted gaseous cauldron called the Crab Nebula.

Unlike the mathematical and monolithic universality which characterized the scientific philosophy emergent from the Western European Renaissance, the explanations tendered for the considerable array of celestial phenomena by

non-western cultures as well as those of pre-Renaissance Europe and the Mediterranean were far more qualitative in nature and represented a diversity of ingenious viewpoints that were nearly as numerous as the cultures from which they sprang. Generally such explanations appear in a given culture in the form of myths, legends, and folklore, and pay considerable homage to the observed characteristics of the sky and its resident objects. As such, they represent the beginning attempts on the part of human beings to provide rational explanations consistent with observations for the variety of events which occur in the physical world, thereby making that world more comprehensible.

Perhaps the most familiar example of this process in action is to be found in the myths and legends pertaining to the fixed stars. Out of the more or less random distribution of stars in the night sky, one can imagine a variety of figures, shapes, and patterns not unlike the variety of faces and forms that one often fancies in the puffy clouds of a springtime sky. In some instances, a given pattern of stars can bear a striking resemblance to a familiar terrestrial entity. For virtually every culture, such similarities were not fortuitous, but in fact were intrinsic characteristics of the sky which were significant and demanded explanation. The most common approach was to regard the sky as a kind of "Celestial Hall of Fame" into which various legendary characters from a given culture's folklore had been inducted for various reasons. Such "inductees" thus became figures outlined in stars or constellations. The outline of some of the constellations are so compelling in their shapes that a variety of far-flung cultures would often envision very similar portraits for a given star group. Thus, the stars of the highly prominent wintertime constellation of Orion, for example, seem to outline a very fit and trim individual possessed of considerable physical strength. Thus Orion, the mighty hunter of Greek mythology is also al-Babādur (The Strong One) for the Arabs, the great hunter "Bull of the Hills" for the Blackfoot Tribe of the western Canadian plains, and the "Slender First One" to the Navajos of the American southwest. As one might expect,

there is also a considerable amount of variation in the sky pictures of various cultures. Even though the J-shaped array of summertime stars which we call Scorpius the Scorpion has been widely depicted as a celestial version of its earthly arachnid namesake, there are many other interpretations of this asterism from other cultures. The Polynesians, for example, saw this star group as the fishhook of their great hero Maui, while the Chinese viewed it as the noble Azure Dragon, the Bringer of Spring. To the Mayas of Central America these stars represented the death god Yalahau, the lord of blackness and waters.

The constellations through which the sun, moon, and planets travel in their respective journeys about the celestial sphere were quite naturally assigned a particularly significant status as the constellations or signs of the zodiac. Traditionally there are 12 such constellations, each of roughly equal extent along the zodiac, and which include Aries the Ram, Taurus the Bull, Gemini the Twins, Cancer the Crab, Leo the Lion, Virgo the Virgin, Libra the Scales, Scorpius the Scorpion, Sagittarius the Centaur-Archer, Capricornus the Sea-Goat, Aquarius the Water Carrier, and Pisces the Fishes. In addition to the standard 12 constellation zodiacs employed by a majority of the world's cultures, the zodiac has been variously divided throughout human history into as many as 28 constellations by the Chinese and as few as six by the early Euphratean cultures. The denizens of the zodiac exhibit a considerable variation from culture to culture. The Aztec zodiac was graced with the starry presence of a frog, a lizard, a rattlesnake, and a jaguar, while that of the Incas contained a tree, a bearded man, a puma, and the sacred cantua plant.

Numerous explanations were offered for the observed movement of the sun, moon, and planets along the zodiac, virtually all of which centered on the basic idea that only gods and goddesses could possess the power to move among the stars. In the case of the sun the concept was further reinforced by the fact that to look directly on the face of the sun's disk was to incur the sun deity's wrath in the form of severe

damage to one's eyes. Thus the sun was the sun god Amon-Ra to the Egyptians and the sun goddess Amaterasu to the early Japanese, and so on.

Eclipses and conjunctions in the sky have also inspired a number of mythologically based explanations. In the Hindu culture, for example, the mortal Rāhu is said long ago to have attempted to partake of the forbidden nectar of immortality. The god Viṣṇu was told of Rāhu's transgression by the sun and moon, and as punishment Viṣṇu proceeded to decapitate Rāhu. Ever since, Rāhu has sought to take vengeance on the sun and moon by pursuing them across the sky in an attempt to eat them. Once in a while, at the time of an eclipse, Rāhu actually catches either the sun or the moon and attempts to devour his prey. As the sun or moon is devoured, it gradually disappears into Rāhu's throat for a time before reappearing at the base of his severed neck as Rāhu attempts to swallow. The entire event is observed here on the earth as an eclipse of the sun or moon.

The sky watchers of antiquity were able to identify a number of basic characteristics relating to the background objects of the celestial sphere. The recognition of the variety of intrinsic colors that characterize the stars, for example, is manifested in names for stars such as the Arabic *Qalb al' Aqrab* (Heart of the Scorpion) for the bright red star Antares located at the center of Scorpius and the Hindu *Rohini* (Red Deer) for the ruddy star Alphard in the chest of the constellation of Hydra the Sea Serpent.

Bright stars near the celestial poles have held great meaning and significance to the watchers of the sky. In the third millennium BCE the north celestial pole was located in the constellation of Draco the Dragon near a second magnitude star called Eltanin. Because the heavens of the day appeared to rotate about this star, it was quite literally regarded as an object of pivotal importance. As a result, Eltanin was worshipped by a number of cultures, including the Egyptians who used this star to align a number of their important buildings and structures. As the earth's axis of rotation has precessed, other stars have taken on the mantle of Pole Star, most notably by the stars Thuban in the constellation of Draco and Kochab

in the constellation of Ursa Minor, the Lesser Bear, and in more recent cultures by the star Polaris at the tip of the tail of Ursa Minor. Both Kochab and Polaris were regarded by the Chinese as Da Di the Great Imperial Ruler of the heavens, about whom the other stars circled in homage. The Pawnee tribe of the American plains named Polaris "The Star That Does Not Walk Around." To the Pawnee this star was related to the god Tirawahat, and as such, was chief over all the other stars. It was this star that saw to it the other stars did not lose their way as they moved across the sky.

Attempts to explain the true nature of the diffuse objects that dot the sky are understandably less prolific in light of the difficulties that are often encountered in observing them. The major exception is, of course, the Milky Way. Of the diffuse objects detectable in the heavens with the unaided eye, the Milky Way is far and away the most extensive and prominent. This delicate band of light which is also highlighted by an array of brighter stars has thus inspired a variety of explanations which include its portrayal as a celestial river by the Chinese and Japanese, as a Path of Souls to an eternal home by the Algonquin tribe of the Lake Ontario region of southern Canada, and as a band of glowing cinders by which one could find one's way home when lost in the darkness by the Bushmen of Africa's Kalahari Desert.

As imaginative and rational as they were, however, the explanations advanced by different cultures for the variety of celestial phenomena observed in the heavens generally became intertwined with the religious beliefs and societal mores of these cultures. As a result, there was a marked tendency for the explanations of celestial phenomena to take on dogmatic qualities in which they were seldom questioned or challenged by alternate points of view. Moreover, the lack of a telescopic astronomy placed severe and fundamental limitations on the level of insight that was possible regarding the nature of celestial objects. Thus the explanations proposed for various celestial phenomena tended to remain largely unchanged in a given culture, and whatever changes that did occur were not so much the

result of additional observational insights, but rather due to a gradual evolution brought on as these explanations were passed on from generation to generation or from culture to culture. Even while armed with an impressive instrumental technology, however, human beings still continue to struggle with questions relating to the fundamental nature of what we see in the sky.

Certain observable aspects of the heavens readily lend themselves to practical usage here on the earth, and the greatest levels of achievement enjoyed by non-western astronomers have come in the discovery, recognition, and application of these characteristics. Systematic observations of the sky reveal, for example, that many celestial phenomena, most notably the diurnal and annual motions of the sun and the cycle of lunar phases, occur with precise and predictable regularity. This observable fact of the heavens has thus been employed by cultures worldwide as a method of accurate time keeping.

The diurnal rising and setting of the sun, with its alternating cycle of daylight and darkness, is the shortest and most convenient unit of astronomical timekeeping, and as a result human beings the world over have employed it, quite literally, as an integral part of their daily lives. A second, much longer unit of astronomical time is defined by one complete journey of the sun around the ecliptic. This annual astronomical cycle is of considerable importance owing to the fact that it is intimately related to the cycle of seasons which occur here on the earth. The cycle of seasons, in turn, is virtually identical to the cycle of vegetative growth and those of some animal activity and migrations. Thus agricultural methods and hunting techniques developed by various cultures were necessarily tied deeply to the cycle of seasons and the sun's annual journey along the ecliptic. Intermediate in length between the day and the year is the time interval required for the moon to pass through one complete cycle of its phases. The lunar cycle is particularly attractive as a timing cycle due to the fact that the ever-changing shape of the moon is readily observable on a daily basis. Sequences of shapes inscribed on Cro-Magnon cave walls and artifacts strongly suggest their use as lunar phase timing

devices in just this fashion. Similar sequences carved by the inhabitants of Nicobar Island in the Bay of Bengal are known with certainty to be employed for this purpose.

Unfortunately these cycles are not quite numerically compatible with each other. For example, there are about 365 days in a year, but in reality it takes the sun precisely 365.242199 days to complete one cycle around the ecliptic. Similarly there are 29.530588 days to a cycle of lunar phases and 12.36827 cycles of lunar phases in a year. These discrepancies can create difficulties if one wishes to reckon the time of the year, the start of a given season, or the date of an important religious holiday by simply counting the number of days which have elapsed from some defined starting point such as the day of a solstice or equinox. If one counts the number of days as the year progresses, for example, one would find that after 365 days had passed, the sun would not quite yet have completed its journey around the ecliptic, and after 366 days had elapsed, the sun would have moved slightly past one complete cycle. Over several years' time such an effect can add up to a significant discrepancy between the sun's actual position along the ecliptic and the position dictated by the day count. As a result, a variety of schemes, called calendric systems or calendars, have been developed by various cultures around the world which are designed to synchronize two or more astronomical cycles. The most familiar of these is the addition of 1 day to our calendar every fourth or leap year in order to keep the day count in a given year in agreement with the sun's actual position along the ecliptic.

A number of ingenious techniques were developed by various cultures to monitor the astronomical timekeeping process. The Aztec Temple Mayor, now buried beneath modern Mexico City, was designed in the fifteenth century with two spires that provided a V-shaped notch through which the rays from a sun rising at the time of an equinox shone on to the temple of Quetzalcoatl. At no other times of the year would a rising sun produce this effect. Thus the Aztec temples served quite nicely and deliberately as a device with which the Aztec calendar

could be corrected whenever necessary. Similar structural alignments are to be found at Stonehenge in England, in the temples of ancient Egypt, and among the buildings of the ancient peoples of the American Southwest. The Mayas of ancient Mesoamerica developed not only astronomical alignments for many of their structures, but also an incredibly accurate but somewhat complicated astronomical calendar which was based on the annual solar cycle and the synodic period of the planet Venus. The Maya calendar was accurate to within 1 day every 5,000 years. By contrast, the simpler Gregorian calendar used by contemporary society is accurate to within 1 day in 3,300 years.

In addition to the structural alignments, various cultures have also employed natural terrain as calendar correctors. On the top of Fajada Butte at the mouth of Chaco Canyon in the American Southwest, for example, there stand three rock slabs, each of which is about 3 m in height. On the rock wall behind these slabs a first millennium AD people called the Anasazi carved a spiral petroglyph in such a way that precisely at noon of the day of the summer solstice, a dagger-shaped beam of sunlight would neatly slice the petroglyph exactly through its center. Through this clever manipulation of sunlight, the Anasazi were able to mark the time of the summer solstice precisely.

The Hopi and Zuni tribes, also of the American Southwest, make use of a so-called sunrise horizon calendar. As the sun moves along the ecliptic, the points of sunrise and sunset along the horizon at a given location exhibit an annual cyclic shift in which the sunrise and sunset points appear to migrate along the horizon from south to north while the sun is moving from the winter solstice to the summer solstice and then north to south along the horizon while the sun is moving from the summer solstice to the winter solstice. As the sunrise and sunset points pass over various key landmarks along the horizon, each passage is taken as a signal to begin the appropriate agricultural activity such as planting various crops, harvesting, etc.

In addition to timekeeping, earth-sky relations can also be employed to find one's way about the

surface of the earth. Such techniques are referred to overall as celestial navigation and have been of considerable importance to human cultures, particularly those which are maritime in nature. There are a number of aspects of the heavens which readily lend themselves as navigational aids. As the earth spins on its axis, for example, a star at or near the celestial pole will not appear to change its position in the sky significantly. More importantly, the point on the horizon directly beneath such a star will also remain in a relatively fixed position as well. Thus for observers in the northern hemisphere, the relatively bright star Polaris is located very close to the north celestial pole, and the point on the horizon directly beneath this signpost star has been used for centuries by northern hemisphere peoples to mark the direction we call north.

Other cultures took advantage of the fact that the angular distance of the pole star above the horizon as well as the locations of the rising and setting points of bright stars and constellations along the horizon changed with one's location on the earth's surface. Thus the Caroline Islanders of the central Pacific skillfully navigated by means of this star compass in which 32 points on the horizon were defined by the rising and setting points of bright stars and constellations such as Vega, the Pleiades, Antares, and the Southern Cross. The Polynesians employed a device called the sacred calabash, which was a gourd into which four holes were bored at the same height near the neck. The gourd was then filled with water to the level of the holes. Using the water level as a horizon, altitudes of stars were then measured by sighting through one of the holes over the opposite edge of the gourd. Thus armed with what was in effect the equivalent of our modern sextant, the Polynesians became most adept at deep-water navigation.

Systematic observations of the heavens also reveal that there exist a number of correspondences between celestial events and configurations and natural phenomena here on the earth. For example, the Egyptians recognized that the annual flooding of the all-important Nile River was at hand when the bright star Sirius made its heliacal rising or first appearance out of the

predawn solar glare. The Incas of the South American Andes Mountains noticed that the cantua plant blossomed beautifully each year when the sun was located in our zodiacal constellation of Cancer, but which they named appropriately from their observations as the asterism of the sacred cantua plant. The heliacal risings of the bright stars Rigel, Aldebaran, and Sirius served to warn the tribes of the high plains of western America that cold weather was at hand. In light of such readily observable earth-sky correspondences, it was very logical to assume that similar correspondences exist between celestial phenomena and human affairs. Thus evolved the endeavor which we now call astrology.

Whether the astrological leap of logic from earth-sky to human-sky correspondences is a valid one has, of course, been a topic of considerable debate for many centuries, and since the 1600s the premise that such human-sky correlations exist has been emphatically rejected by western science. Nevertheless, astrology, more so than either timekeeping or celestial navigations, demands access to careful and ongoing observations of the entire heavens for the purpose of interpreting the significance here on earth of what is seen to occur in the sky, and whenever possible, to predict future events in the sky as well. Thus a well-developed [▶ astrology in China](#) was certainly an important factor in the preparation of the earliest known star catalog in the fourth century BCE, and in the recording of a variety of celestial events, most notably the transitory appearances of sunspots and astrological omens such as comets, which were referred to as *huixing* (broom stars or sweeping stars) and of novae and supernovae explosions, which were called *kexing* (guest stars or visiting stars). So detailed were the records of the Chinese, Japanese, and Korean observations of the supernova event of AD 1054, for example, that modern astronomers were easily able to identify its present remains as the Crab Nebula in the constellation of Taurus, despite the fact that the event went virtually unobserved and unrecorded in Western Europe.

From some cultures, most notably those of the Mayas, Egypt, China, and the Islamic world,

careful observations of the sky combined with centuries of relative social and political stability to make possible the discovery of much more subtle and long-term astronomical cycles. The Mayas, for example, were aware of the long-term reappearances of the planet Venus and built the planet's 584-day synodic period into their calendar. Both the Chinese and Islamic observers were aware of the fact that the lunar nodes, or the points on the celestial sphere where the moon's orbit crosses the ecliptic, drift in a westerly direction along the ecliptic at a rate of one complete revolution every 18.6 years and used this knowledge to predict the occurrences of both lunar and solar eclipses.

The Chinese and Islamic observers also recognized that the sun's equinox points drift in a westerly direction along the ecliptic at a rate of nearly 1° per year and made appropriate adjustments in their respective star catalogs and calendric systems in order to account for the protracted effect of this equinoctial precession. Awareness of the shifting equinoxes may have also been the province of the Egyptians as well. A number of additions and reconstructions are found to exist in Egyptian temples and other structures which strongly suggest an architectural response to just such long-term changes in the positions of the equinoxes.

Astronomy in China

Ho Peng Yoke

Chinese astronomy became a subject of long debate among historians and astronomers in the first half of the twentieth century. Some based their argument on the *Shujing* (Book of Documents) and concluded that Chinese star clerks had already made astronomical observations between 2000 and 3000 BCE. Richard Schlegel even asserted that they knew about the 28 lunar mansions as long ago as the year 1600 BCE. Others doubted the reliability of the records in the *Shujing* claiming that Chinese astronomy could not have originated earlier than 500 or 600 BCE. Some said that Chinese astronomy originated from India, others said from Arabia, and there were yet those who said that it was from Mesopotamia. Joseph Needham, for example, favors a Mesopotamian origin.

Recent archaeological studies carried out in China have thrown more light on early Chinese astronomy and enabled scholars to re-examine some of the old interpretations. Archaeologists have been hard at work during the last two decades to establish the Xia dynasty, which, according to tradition lasted from the twenty-first century BCE to the sixteenth century BCE, and which has until now been regarded as legendary. They have yet to recover written records of that period. Erlitou in Henan province, where bronze vessels dating back to the year 1700 BCE

were recovered in 1971, is one of their important sites. Even the records in the *Shujing* have recently been re-examined by comparison with computed ancient astronomical phenomena.

In the oracle bone writings we can find records of eclipses, novae, and names of stars and some asterisms. The records indicate that the Yin people between the fourteenth and twelfth centuries BCE were already using a lunisolar calendar, where 1 year consisted of 12 moons or lunar months of either 29 or 30 days each, with an extra month known as the intercalary month added about every 3 years. From about the sixth century BCE until the use of the telescope for astronomical observations in Europe in the seventeenth century, Chinese star clerks kept the most consistent and continuous astronomical records on eclipses, comets, novae, sunspots, and aurora borealis in the whole world. Star catalogs were produced during the Warring States period (481–221 BCE) by ► [Gan De](#), Shi Shen, and Wu Xian. Chinese astronomical records have found many applications in modern astronomy. One application is in the calculations of the period of Halley's comet. The Crab Nebula has been identified with the supernova observed in China in the year 1054. The first pulsar was discovered in 1967. It was found to be near a site where a "guest star" was recorded by the Chinese. A "guest star" in Chinese astronomy could refer to a supernova or nova, but it could also mean a comet or even a meteor, depending on the context. In this case it refers to a supernova or nova. As a result some astronomers made use of Chinese records in their attempts to discover other pulsars. Chinese records on sunspots have been used to determine sunspot cycles, and recently they were used in the study of the variation of the earth's period of rotation. There are many other applications for Chinese astronomical records, such as in a recent study of the Star of Bethlehem in the Bible.

There has been a prolonged dispute since the last century over the question of the origin of the 28 Chinese lunar mansions. These are 28 asterisms distributed along the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course). The moon changes its position among the stars night after night, and appears

successively in each of these asterisms, appearing from the earth as if it changes its lodging each night. Hence they were known as lunar mansions or lodges. Chinese astronomers also picked one of the stars in every lunar mansion as a reference point from which distances of other stars in its vicinity were measured. The stars used as reference points were called determinant stars. In ancient Hindu astronomy there were 27 *nakṣatras*, each of which had a principal star (*yogatarā*). Nine of the *yogataras* are identical with the Chinese determinant stars. Some thought that the lunar mansions and the *nakṣatras* had a common origin, often with Sinologists and Indianists taking opposite sides. Before a conclusion was reached came a third contender, the *al-manāzil*, the moon-stations in Muslim astronomy. Then it was argued that Muslim astronomy was predated by Hindu astronomy. During the middle of the twentieth century the most favored candidate was Mesopotamia, from which ancient Chinese astronomy and others were thought to be originated. This is the view favored by Joseph Needham. The argument against China's favor until then was that all the names of the 28 lunar mansions were not found earlier than the fourth century BCE. However, in the year 1978 the names of all the 28 lunar mansions were found inscribed on the lid of a lacquer casket of the early Warring States period, showing that the 28 lunar mansions were already there in China not later than the fifth century BCE. Chinese archaeological discoveries in the second half of this century and recent archaeological excavations carried out in India have also shown that both Chinese and Indian civilizations existed much earlier than they were thought. Whether the lunar mansions in Chinese astronomy were influenced by the Hindu *nakṣatras* or whether it was the other way round is an open question. Perhaps there was no influence between the two systems at all. The important thing in the study of history of science and civilization is to learn about mutual exchange of ideas among different cultures rather than to engage in futile disputes, claiming priorities and making scores in meaningless contests, in which there is no prize for the winner other than false pride.

The earliest existing Chinese documents on astronomy are two silk scrolls discovered in the Mawangdui tombs in Changsha, Hunan province in the year 1973. One of them, the *Wuxingzhan* (Astrology of the Five Planets) contains records of Jupiter, Saturn, and Venus, the accuracy of which suggested the use of the armillary sphere for measurement. These records were made between 246 and 177 BCE. The other, the *Xingxiangyunqitu* (Diagrams of Stellar Objects and Cloud-like Vapors of Various Shapes) illustrates different types of comets. Among the ancient astronomical instruments discovered by archaeologists are the bronze clepsydra from the tomb of Liu Sheng of the second century BCE and a bronze sundial of the Eastern Han period (25–220). The title of an early Chinese book on astronomy and mathematics, the [► Zhoubi suanjing](#) (Mathematical Manual of Zhoubi), calls to mind either the Zhou dynasty or the circumference of a circle, and the vertical side of a vertical right-angled triangle. The book contains the so-called *Zhoubi* or [► Gaitian](#) cosmological theory in which the heavens are imagined to cover a flat earth like a tilted umbrella, and shows paths for the sun at different seasons of the year. From the positions of the stars and planets mentioned in the text, Japanese scholars established a period between 575 and 450 BCE for the observations and inferred that the book was written within the same period. Christopher Cullen recently showed that the book could well be a work of the early first century.

During the second century [► Zhang Heng](#) (78–139) constructed an armillary sphere as well as a seismograph for making astronomical observations and for detecting the direction of earthquakes. An armillary sphere consisted of a system of rings corresponding to the great circles of the celestial sphere and a sighting tube mounted in the center. With such an instrument Chinese astronomers could measure the positions of heavenly bodies. The mounting of the Chinese armillary sphere deserves special attention. As pointed out by Needham, it has always been equatorial unlike its counterpart in Europe which was ecliptical, but only changed to equatorial in modern telescopes. The new armillary

sphere made by Zhang Heng resulted in more accurate observations and better star maps.

An important role of Chinese astronomy was calendrical calculation. The emperor regarded calendar making as one of his duties associated with the mandate that he received from Heaven. The Chinese calendar took into account the apparent cycle of the sun and the cycle of the moon, both of which, as we know, cannot be expressed in an exact number of days. The astronomer responsible for constructing a lunisolar calendar had to make accurate observations of the sun, the moon, and the planets, but however accurate his observations and his calculations, his calendar would sooner or later, in just a matter of decades, get out of step with observations. Hence throughout Chinese history no less than 100 calendars had been constructed. Besides, sometimes there were also unofficial calendars adopted in certain regions in China. During the seventh century Indian calendar-making made its presence felt in China. We can read the names of a number of Indian astronomers and calendar experts who lived in Changan, the capital of Tang China.

In the early days of the Tang dynasty the calendar officially adopted was the *Lindeli* calendar constructed by the great early Tang astronomer, mathematician and diviner [► Li Chunfeng](#) (602–670). By the early eighth century a new calendar became overdue. Eventually the old calendar was replaced by the *Dayanli* calendar constructed by the Tantric monk Yixing (683–727). Yixing's secular name was Zhang Sui. He is regarded as the most outstanding astronomer of his time for his recognition of the proper motion of the stars. In the year 721 the Tang emperor Xuanzong entrusted Yixing with the task of constructing a new calendar. To do this he constructed new astronomical instruments, including an armillary sphere moved round by wheels driven by water, and he also carried out a large scale research project to measure the length of the earth's meridian. He employed the method of difference, involving equations of the second degree, as well as the method of the remainder theorem in the *Suanzi suanjing* to calculate his new calendar.

From the late seventh century Indian Tantric monks had also come to reside in the Tang capital. Later Yixing made frequent contact with them and assisted them in the translations of some of their *sūtras* into Chinese. Yixing could have acquired from them some knowledge of astrology and mathematics, including the idea of a spherical earth and the sine table. There were then three clans of Indian calendar experts living in the Tang capital, namely the Siddhārtha clan, the Kumara clan and the Kaśyapa clan, of which the Siddhārtha clan was the most active and famous. At least two members of that clan had served as Directors of the Astronomical Bureau. The most distinguished member was Gautama Siddhārtha, who constructed an iron armillary sphere when he was director and translated the *Navagrāha* calendar into Chinese in the year 718. Most important of all, he compiled the *Da-Tang Kaiyuan zhanjing* (Prognostications Manual of the Kaiyuan Period of Tang Dynasty) between the years 718 and 726. The word *Navagrāha* means the “Nine Luminaries,” namely the Sun, the Moon, Mercury, Venus, Mars, Jupiter, Saturn, and two imaginary planets *Rahu* and *Ketu*. Although this calendar was never adopted in China, it found its way from there to Korea, where it was used for a period of time.

During the Song dynasty (960–1279) astronomers made more accurate astronomical observations using new and larger armillary spheres. They constructed several such instruments, the most famous of which was that made by Su Song (1020–1101). It was an armillary sphere driven by a water-wheel using the principle of escapement. A full-scale study of Su Song’s instrument is given in Joseph Needham’s *Heavenly Clockwork*. Su Song’s instrument was both an armillary sphere and a clock, but it was known only as an armillary sphere. Hence until it was pointed out by Needham, Price, and Wang Ling, nobody knew that the clock already existed in China when Matteo Ricci introduced the clock in the late sixteenth century.

Astronomy during the Mongol period (1271–1368) was closely connected with the name of Guo Shoujing (1231–1316), the last of the great traditional Chinese astronomers. The

Shoushili calendar that he constructed was the most advanced and accurate calendar ever produced in traditional China. It was made possible by the precise instruments he built and the method of finite difference he used in his calculations. This was also the time when astronomers from the Arab world came to work in China. The Muslims were still active in the Astronomical Bureau when the Jesuits came toward the end of the sixteenth century. The Jesuits arrived at a time when Chinese astronomy was in a state of stagnation, when no one with the knowledge and skill of Guo Shoujing could be found. The Chinese learned pre-Copernican astronomy from them. Modern astronomy came to China only around the middle of the nineteenth century. It did not take long for Chinese astronomy to join the mainstream of modern astronomy. Just as Nakayama Shigeru said that the history of Japanese astronomy was the history of Chinese astronomy in Japan, Chinese astronomy has already become modern astronomy.

Astronomy in Egypt

Gregg De Young

The American University in Cairo, Cairo, Egypt

We have few written records dealing explicitly with the heavens, and those that we possess are usually derived from the Greek astronomical tradition and therefore are very late in Egyptian history. Thus, in order to assess the astronomical knowledge of ancient Egypt, we rely on such limited pieces of evidence as “diagonal calendars”

that decorate some Middle Kingdom (ca. 2150–1780 BCE) coffins, orientation of tombs and pyramids relative to the cardinal compass points, and astronomical ceilings (and their accompanying inscriptions) used in New Kingdom (ca. 1550–1085 BCE) temple or tomb decorations.

Evidence from the region of Nabta Playa indicates that systematic observations of the heavens were already well developed during the predynastic period (prior to 3100 BCE) of Egyptian history. Here, an ordered array of stones grouped in a rough circle around a central stone are reminiscent of the artificial arrangement of megaliths at Stonehenge, although the Egyptian arrangement is much older.

One of the primary incentives for study of the heavens in ancient Egypt was the necessity to establish the cultic calendar on a firm basis. This cultic calendar, growing out of less formal agricultural and ritualistic calendars, defined the beginning of the year using the heliacal rising of Sothis (modern Sirius). For administrative purposes, a civil calendar was superimposed upon the older luni-stellar cultic calendar. The determination of the administrative year was not defined by astronomical observations, however, but by counting off 365 days from the beginning of the year. Because the civil year contained exactly 365 days, it was typically out of step with the natural or solar year. The two coincided only every 1,460 astronomical years (the so-called Sothic cycle).

The determination of cultic celebrations, however, continued to be based largely on lunar phenomena. In order to correlate the two calendars, the Egyptians used the observation that there are very nearly 309 lunar cycles in 25 civil years. In general, any two successive lunar months had 59 solar days, but every 4 years, the last two months were given 60 days, a correction reminiscent of our leap year. This correlation allowed the priests to predict with fairly consistent accuracy where lunar festivals should fall within the civil calendar, obviating the necessity to observe the heavens in order to determine the time for a particular festival.

The civil year was divided into 36 “decans” of 10 days each, to which five epagomenal days

were added. These decans are represented in the diagonal calendars or star clocks depicted on several Middle Kingdom coffins, presumably as a way for the deceased to know when specific spells needed to be recited during the journey to the afterlife. Such star clocks may also have been associated with nightly timekeeping in temples for religious observance. In order to predict the coming of the dawn so as to be prepared to perform essential temple rituals, each hour of the night was associated with one or more bright stars whose heliacal rising would signal the beginning of each hour of the night. Because the sun moves slightly slower than the stars in its apparent circling of the Earth, any chosen star will rise farther and farther in advance of the sun, so that it is an effective indicator of the first hour of the night only for about 10 days, after which the asterism which had originally indicated the second hour now introduced the first hour of the night.

In the New Kingdom, the focus shifted from heliacal rising of each decan star to its zenith transits – an easier phenomenon to observe. But this shift required that the decan asterisms be redefined. These observations apparently involved noting the position of stars relative to the body of an assistant (e.g., when the star is located above his right eye). Charts illustrating this method are seen in the tombs of Ramses VI, Ramses VII, and Ramses IX.

It has often been noted that pyramids, and especially the pyramids of the Giza plateau, as well as numerous tombs and temples, seem to be aligned with the cardinal compass directions. The precision of such alignments points to an astronomical determination of the cardinal directions, although we do not know exactly how this was done. The older hypothesis was that a level artificial horizon was constructed, against which the rising and setting points of a given star would be marked. Bisection of the angle between these two sightings, as measured from the center of the artificial horizon, determines true north. This technique, although possible, appears cumbersome. A somewhat simpler method would have been to erect a gnomon perpendicular to the Earth and to construct around it a circle of arbitrary

radius. Mark the two points at which the shadow of the gnomon touches this circle, once before noon and once after noon. The line bisecting the angle formed between these two observations and the gnomon determines true north. We have, however, no surviving evidence to reveal which of these two procedures the ancient Egyptians used. (It is also fair to say that many temples and tombs are not so precisely oriented – many merely face the Nile, which flows roughly from south to north, without regard for local geographical variations.) Although most temples appear to be aligned east and west, two directions that are associated with solar worship, others are explicitly oriented to stars, especially Sothis.

The scanty surviving evidence suggests that the Egyptian observer of the heavens used only the simplest of observational tools, and even these may not have been used extensively prior to the New Kingdom period (ca. 1550–1085 BCE). Nocturnal observations typically involved a *merkhet* (a palm rib notched at its wider end, used in conjunction with a plumb line) to determine the zenith transit of a celestial object. Daytime observations generally involved determination of solar altitude using length of shadows. These measurements were sometimes made using a horizontal graduated bar, with a small perpendicular block at one end to cast a shadow on the horizontal bar. Herodotus reports that the Egyptians knew sundials, but surviving evidence favoring that view is scanty. The shadow clock, however, suffers from the same problems as the sundial. Both are constructed to divide the day into equal parts, although the inclination of the Earth's axis creates unequal lengths of daylight throughout the year, complicating any attempt to regulate time through astronomical observations.

When astronomical observations were not possible, the Egyptians sometimes used a water clock similar to a Greek clepsydra to determine hours. Water is allowed to escape from a container of known volume through a small orifice at the base. The interior is graduated to show the lapse of time. The ancient Egyptians apparently did not appreciate that the rate of outflow is not constant. Here, too, we find that

a degree of inaccuracy or indeterminacy seems to have been accepted.

Astronomical ceilings are among the most striking pieces of evidence concerning the ancient Egyptian's knowledge of the heavens. Central to these documents are a group of figures whose composition and orientation change very little with time. These are usually considered to represent the circumpolar constellations, although all attempts to match these figures with visible star groupings, apart from the foreleg (Big Dipper, part of the constellation Ursa Major), have so far been unsuccessful. In addition to these groupings, there are often iconographic and inscriptional references to the naked-eye planets and to individual bright stars (most notably Sothis/Sirius). All of this indicates that the ancient Egyptians were careful observers of the night sky, although probably not overly concerned with reducing these observations to mathematical models of the kind found in Greece.

We know very little about practitioners of astronomy. Only in very rare instances do funerary titles indicate someone who may have observed or studied the heavens for some specific purpose beyond personal curiosity. The evidence indicates, however, that there was a continuing effort to observe and describe celestial phenomena.

Astronomy in Hawai'i

Rubellite Kawena Kinney Johnson

There were two important tasks that drew on ancient Hawaiians' understanding of space and time. One was constructing a ritual calendar for determining the length of the day, week, month, and year; the other was navigating on the seas between island destinations.

The first, calendrics, was the responsibility of the priests, among whom were stargazers called *kilo hoku*, from *kilo* (to observe or to watch), and *hoku* (star). The same stargazers, however, observed more than stars. They knew the sun's

motions and those of the moon and the planets, but the stars were the most challenging.

Let us look at this from the standpoint of the student who starts out in "class," which was a place set aside for men and boys to worship the gods. In a place where men only spoke with one another in the men's eating house, the *hale mua*, the "front" (*mua*) house in the compound of the household (*kulana kauhale*), a young boy began his training in these subjects. Since they were part of required religious training, he found himself within rock-walled enclosures, or temple (*heiau*) grounds set aside for men's worship, the *tabu pule* scheduled through seven nights, *na la kapu kauila*, totalling 56 nights in an 8-month period. The 240-day *tabu* period was followed by 120 days of the *makahiki* season during which taxes (*auhau*) were collected.

No one knows how astronomical subjects were taught, although some information has survived through stories and chants from the migration period of discovery and exploration, with wayfinding practice associated mainly with places visited in ancestral lands to the south. The sun's motion between the north and south and across the equator may have been the first fundamental horizon system to be learned, combined with the observations of stars nearest the rising and setting points of the sun in the morning and evening.

The sun's rising (*hiki*) gives the cardinal direction east its name: *hikina*. When above the horizon, it is *kau*, to be placed or to be hung, but it also means to set, as of the sun afloat westward, *kau lana ka la*. When the sun sets, it "enters" (*komo*) into the world below, so that cardinal direction west is called *komohana*, the "entering" place of the setting sun. When the sun has stopped on its northern journey, that point is called the sun "afloat," *kau lana ka la*. Its daily motion as it arches upward from its eastern azimuth or "pit" (*lua*) to local zenith (*nu'u*) and after noon "declines" (*'au*) is called *ka'a*, *ka'a ka la ma lalo*, the sun moves down. When it crossed the equator, the sun was said to "trample" (*ke'ehi*) the "diaphragm" (*houpo*) of the god Kane (*ke'ehi i ka houpo o Kane*), the sun being the "eyeball" of

Kane (*Kane 'ono*hi o ka la). This is the basic compass, adding north for the right (*'akau*) and south for the left (*hema*) sides of the body.

The days were counted as nights of the moon, and there were two revolutions tracked, one synodic, and the other sidereal. Each "night" was clocked into quarters. The clock began at midnight, called *Kau*, or *Aumoe*, the latter meaning "time of sleep." *Kau* situates the clock on meridian, as at midnight and so also at noon, so the midday was also called *Kau*. When the sun was in the zenith (*nu'u*, *lolo*) it was called *kau ka la i ka lolo*, the "sun was over the brain (*lolo*)." This position of the sun, not only on meridian but in the zenith as well, took place twice in the year – once when the sun was going north, between May and June, and again when the sun was going south, between June and July. People today may call this "Lahaina noon," but generally the zenith sun appears at the southernmost part of the island of Hawai'i, about 19° north about May 15th (although the date is variable). All other "noons" when the sun is on meridian are called *awakea* after Sky Father, Wakea, whose name is synonymous with noon and the center of the celestial equator, called *Ka Piko o Wakea*, the "Navel of Wakea" (Sky Father). *Piko* means "center of the body," which has three such *piko*: one at the top of the skull in the soft spot, the fontanel; one at the navel, and one at the midpoint of the genital area in line with the *piko* in the middle of the skull. When one lies down, then the *piko* at the center of the horizontal body, called the *'opu*, is in contact with navel center of Mother Earth, *Ka Piko o ka Honua*. "The Navel of the Earth," or terrestrial equator, which extended beyond earth into the sky is *Ke Ala i Ka Piko o Wakea* (Path to the Navel of the Sky); *Ka Piko o Wakea* is the celestial equator.

The clock having thus two *Kau*, midnight and midday, is an indigenous concept of the "mean day," by which day and night are divided into equal parts. There were no hours, except the quartering for the night, commencing about sunset (i.e., 6:00 p.m.), called a "corner" (*kihi*), and the next "corner" at sunrise, *Kihi puka*; *puka* means "to emerge," as a celestial body, whether

sun, moon, stars, or planets. Between the kihi corners were the *pili* quarters, meaning “close to,” as in *pili ‘aumoe*, about 9:00 o’clock at night, and *pili puka*, about 3:00 a.m., meaning “close to sunrise.” From these data it appears that the shape of the Hawaiian clock between the two Kihi is angular rather than circular, perhaps a rectangular shape. The day clock is spread out on both sides of noon (Kau, Awakea) by morning (*kakahiaka*), afternoon (*‘auinala*, from *‘au*, “to decline,” as of the sun), and evening (*ahiahi*). Day and night are *ao* (daylight) and *po* (night).

The moon was regarded as feminine, as passive light or a reflection of the goddess Hina, perceived as ruling the tides, as well as growing sea life on and around the living reef. Each night of the moon had a separate name through one synodic revolution of the moon, or that passage from the first crescent perceived in the west until it returned to that point again in 29.5–30 nights.

The new moon, or dark phase, was *Muku* (cut off or severed). Hina, the moon goddess, was thought to have gone into and through the Milky Way (*Ka Wai Ola a Kane*, “Living Waters of Kane”), in which her dying soul (*Mauli*) revived in the life-giving semen of the creator god. Her spirit was the last crescent waning moon (*Mauli*). On the night of Muku, Hina’s spirit was in the Milky Way. After Hina comes through the *Wai Ola a Kane*, the first braid of her gray hair is seen at Hilo after sunset, low on the horizon, alive again. The waxing (*ho’onui*) moon begins at Hilo, moving south until first quarter at ‘Ole, thus:

These ten “nights,” or 10 days, were the first *anahulu* decan week of the month and year. In this circuit of 10 days the lighted part of the moon’s crescent increased as the moon continued southward. This was followed by two more *anahulu* decan weeks of rounding (*poepoe*) of the moon when the lit portion lost its “cusps” (*Ole*, milk teeth) until the fully lit circle, after which it began to wane or “shrink” (*‘emi*) back to the dark phase of new moon (*Muku*).

The ritual period of tabu days during 8 months of the year was coordinated between synodic and sidereal lunations, zenith stars, and azimuths of sun and stars in the ecliptic. [The following is excerpted (and readjusted) from Johnson 2000.]

The first ritual tabu period of the month, called a pule period, was imposed on the night of Hilo and raised on the morning of Kulua. . .

This period of the Ku pule tabu amounted to 2 and 1/2 days, between Hilo, Hoaka, Kukahi, Kulua. . .

During the poepoe rounding decan of the waxing moon, the tabu pule period was called the tabu of Hua, imposed on the night of Mohalu (12th night) and raised on the morning of Akua (14th night), i.e., from Mohalu, to Hua, and Akua. This added 1 and 1/2 more days to the 2 and 1/2 day Ku tabu before first-quarter moon. . .

A tabu pule period was assigned to the god Ka (na)loa. Imposed for 1 and 1/2 days, it began on the night of ‘Olepau and ended on the morning of Ka (na)loa-ku-lua, i.e., from ‘Olepau to Kaloakukahi and Kaloakulua. . .

After Kaloa-pau came the 27th night of Kane when began the tabu pule for this god on 1 and 1/2 days, from the night of Kane to the morning of Maui, i.e., Kane, to Lono, and Maui. While including the 28th night of god Lono, no tabu pule was set aside for the god Lono during the month.

The tabu period was in force for 240 days and relaxed for 120 days, beginning in the month of October, or the last month of the summer (Kau) season. This anticipated the shift of prevailing winds from the southwest (Kona) and the beginning of the agricultural year, *makahiki*, in November when the Pleiades star cluster (*Makali’i*) was expected to rise above the eastern horizon in the evening, opposite the sun and after the new moon in November.

David Malo, native Hawaiian scholar at Lahainaluna Seminary in the mid-nineteenth century, said:

The makahiki period began in Ikuwa, the last month of the period called Kau, and the month corresponding to October, and continued through the first 3 months of the period Hooilo, to wit: Welehu, Makalii and Kaelo, which corresponded with November, December, and January. . .

There were 8 months of the year in which both chiefs and commoners were wont to observe the ordinary religious ceremonies, three of them being the Hooilo months of Kaulua, Nana, and Welo, corresponding to February, March, and April; and five, the Kau months of Ikiiki, Kaaona, Hinaialeele, Hilinaehu, and Hilinama, which corresponded to May, June, July, August and September. (Malo, 1951, p. 141)

The moon calendar was a coordination of synodic revolutions of the moon between Hilo and

Muku of 29.5–30 days/nights of the month with sidereal lunations of 27.3 days/nights based on the transit of the meridian by a star, probably during quarter moon ('Ole nights) until the next transit.

What is the significance of the sidereal/synodic count in lunations of the moon's revolution around the earth and sun in 1 year? (1) The principle of the sidereal count is that, with respect to a star on the meridian, the moon's period of revolution around the earth is 27.3 days (Kane is the 27th night of the lunation). (2) The principle of the synodic count says that from its starting point at new moon, until it returns to that point, the moon revolves around the earth once every 29.5 days. Thus, (3) For every sidereal revolution of the moon around the earth in 27.3 days, the earth moves 1/13th of its orbit around the sun (with respect to a star on the meridian).

What was then the mode of intercalation to coordinate the sidereal with synodic lunations? We may only infer how that would have been done.

1. If we erase the 1/3rd fraction (Kane = 27 nights)
2. Then: 27 days $\times$ 13 months = 351 days = 1 sidereal year
3. We intercalate the fortnight (14 days) = 365 days = 1 tropic year
4. If we include the 1/3rd fraction, then: 13 sidereal months = $27.3 \times 13 = 351.39$ days
5. Intercalate 13.86 days = 365.25 days

This segment in *Kumulipo Mind* explored the relationship between the indigenous system and that borrowed from nineteenth century European calendrics after contact:

This formula provided an iconography of time in the sacred structure of temples and ritual schedule to a numerology, such as 16 sidereal lunations is equivalent to 32 fortnights ($13.5 \text{ days} \times 16$) and 432 days, the significance of which has been explored in the discussion of the decan system and tropic. (Johnson, 2000, p. 111–112)

Perhaps by pure chance the formula appears again in the Babylonian use of base 60 in the division of time connected to the earth's rotation

on its axis such that 15° equal 1 h circle of the earth's rotation, thus:

1. 1 min = 60 s
2. 60 min = 1 h
3. 1 h = 3,660 s
4. 24 h = 1 day
5. 1 day = 1,440 min
6. 1 day = 86,400 s
7. 12 h = 43,200 s
8. 6 h = 21,600 s
9. 3 h = 10,800 s
10. 1 1/2 h = 5,400 s
11. 3/4 h = 2,700 s
12. 3/8 h = 1,350 s

By this may be comprehended that the basic determination is made that the "turning" (kahuli) of the earth on its axis, or because of its rotation, creates the meridian, called *kaupoku o ka hale*, the 'ridgepole of the house' (meaning the house of God, the heiau), cutting the night/day into two halves by which celestial bodies ascend to the zenith (nu'u) and transit by descent to the horizon.

The motion, however, is the earth rotating on its axis, which could not be seen except as a change.

O ke au i kahuli, wela ka honua
 O ke au i kahuli, lole ka lani. . .
 In the time of turning over and around,
 The earth became hot; the sky changed
 [Wa Akahi, Kumulipo].

The passage of time is then measured by equalizing time on either side of the meridian, as between noon and midnight, or midnight to midnight, or noon to noon. The clock is geared to time elapsing between meridians, rather than between sunset and sunrise, or vice versa. The Hawaiians, like the Babylonians, had discovered the "mean day". By it they set their clock to keep track of the length of one day as from one midnight to the next.

The apparent movement of the sun was observed along the horizon between November and February as a slow period (actually, of the earth's orbit around the sun) and the fast sun between March and October. Perhaps the ancients had determined when the sun appeared to have crossed the celestial equator sometime in

April and again in October, or the minor axis of the ecliptic, the major axis between January and July constituting the anomalistic, rather than the tropic year (i.e., the orbit of the earth around the sun).

This was essentially the story of demigod Maui lassoing the sun to make it go more slowly during the winter months by tying down all 16 legs of the sun to a *wiliwili* tree on the western slopes of Haleakala in east Maui. The sun's motion north and south between the solstices was perceived as the motion of a spider (*ke ala a ke ku'uku'u*) as it laid down a web of the celestial grid through which the stars are tracked in their fixed courses from east to west in the night sky.

Finally, as in classic cosmologies of the Mediterranean and Eurasian systems, the sky becomes a pictorialized storyboard conveying by imagery and metaphor the positions and movements of constellations as characters from the ancestral heroic traditions of the past, so that the sky is not filled with nameless lights. The following is part of a continuing quotation excerpted from *Kumulipo Mind*:

The 'way of the spider' is known in Hawaii as the ecliptic, Ke-ala-a-ke-ku'uku'u 'pathway of the spider' (ku'uku'u, 'to let down, as a net') who is called Tukutuku-raho-nui (spider-of-large-scrutum) 'Great Spider', Tahitian (and Tuamotuan) tutelary deity of net-weaving in the Tahaki cycle.

The pathway of this spider was shown on the navigation gourd (ipu makani) diagrammed by Kaneakaho'owaha, counselor to Kamehameha I, in old Hawaii. It had several markings: the celestial equator, Ka Piko o Wakea 'The Navel of Wakea (Sky Father)'; the ecliptic, Ke ala a ke Ku'uku'u 'The Path of the Spider', which was divided into four parts:

1. The limit of the sun's path in the north on the 15th or 16th day of the month Kaulua (June, for Gemini), the summer solstice, Ke Ala Polo-hiwa a Kane "The Black Shining road of Kane"
2. The limit of the sun's path in the south on the 15th or 16th day of the month Hilinama (December, unidentified), Ke Ala Polohiwa a Kanaloa "The Black Shining Road of Kanaloa"
3. The eastern quarter, Ke Ala'ula a Kane 'The Dawning of or the 'Bright (Red) Road of Kane'
4. The western quarter, Ke Ala Ma'awe'ula a Kanaloa 'The Red-Track (as of a spider's thread, from *awe*, strand, thread; 'awe, tentacle) of Kanaloa'

A line was drawn in by burning in (pyrogravure) between the North Star (Polaris) and the Southern Cross, indicating the meridian. From another tradition of the navigation gourd, according to Theodore Kelsey, the night sky was graphed, in the form of a net (koko) woven over the calabash of mesh squares, a grid numbering 24–36 spaces (maka), as of a net ('upena), called na maka o 'Alihi 'the eyes of 'Alihi. Below the rim of the gourd, securing the mesh to the rim, was a red cord of 'olona twine called the 'Alihi, corresponding to the name of Tahaki's loyal cousin and helper, Karihi, who assisted Tahaki in reaching the sky world (Kelsey, in Johnson & Mahelona, 1975, pp. 150–152).

The Hawaiian navigation gourd net which bears the name of Karihi as the supporting red cord, 'alihi, and the 'eyes of Karihi', na maka o 'Alihi, is a parallel to the net of Tahaki fashioned by Tukutuku-raho-nui 'Great Spider' (Tahiti) whose path was outlined between the solstices and equinoxes on the ecliptic.

Tahaki's birth, like that of Maui, was in a West Polynesian home, and the place where Hema (Sema) was 'caught by the 'A'aia' was in Kahiki-west, or Viti, meaning in the direction of Fiji. In the Ulu genealogy, Kaha'i appears in the tenth generation after Maui.

In Hawaiian myth the spider's web as the shape of the spider in the sky is a form of the supernatural hero, Kana, son of Haka-lani-leo and Hina, chief and chiefess of Hilo, island of Hawaii. Kana was the grandson of Uli, the goddess, and Ku. Uli was the sister of the sky god Wakea and Manu'a (god of the underworld). The name Manu'a belongs to Samoa.

Kana is born supernaturally as a rope which was thrown into a pig pen and forgotten. He is the 12th son. The spirit of the cast-away baby visits the grand-mother Uli, and she recovers the neglected rope, putting it into a calabash of water where it grows 40 fathoms in 40 days, or one fathom a day, but no more than 400 fathoms.

In the meantime Kana's older brother, Niheu, who is only half as tall (5 feet) as his ten brothers, is the only person able to lift the 10-fathom 1-yard-long great *ulua* fish. Niheu tells his father he is unable to rescue his mother.

Kana is sought to help Hina because of his superb stretching powers, so Kana is sent by Uli to help Niheu rescue Hina from Keoloewa of Moloka'i. Meanwhile Keoloewa orders the turtles to raise the fortress, Ha'upu, on Moloka'i, higher. Niheu tries to climb it but is distracted by the plover who plucks five hairs from his head, whereupon Niheu falls, breaking his leg. (All of Niheu's strength is in his hair, which is never cut). So Kana employs his bodies to reach Haupu fortress:

...Kana was very angry, for he knew that now they would have a great deal of trouble in rescuing their mother again. Kana turned over in the mats and having thus broken the ropes, stood up. The king saw that this man was taller than his fortress. As Haupu was slowly raised higher and higher, Kana stretched his body, first his human body, then his rope body, next his *convolvulus* (morning glory) vine body, his banana (cordage) body, and last his spider web body. (Fornander, 1969, pp. II: 16–18)

In a Kaua'i variant the motif of Kana's changing the hill by stamping (on) it with his foot (*ke kapua'i a Kana; kapua'i*, measuring foot; (vs.) *wawae*, "foot," as of the body) is repeated. The name of the hills raised by the turtles, both on Moloka'i and Kaua'i, is Haupu:

Kana was afraid that it would reach too high, so he stretched himself up until his body was no larger than a spider's web. When he was tall enough, he put his foot on top of the mountain and crushed it down [Another trait of his demigod is that he possessed two large, staring eyes].

In the tale of Kana the spider's web is the equivalent of the cord kept in a calabash of water. The cord measures out from the calabash, forming a 40–400 fathom rope. This may be interpreted again as the bailing gourd (*Hina-ke-ka*) filled with water and kept on the canoe.

The god of the golden plover, *kolea*, was Lono-kolea-moku, symbolized as a red stone in the heiau foundations at Cape Kumukahi, Puna, Hawaii. The rock was the first in a row of five stones, four of which were called "The Wives of Kumukahi," spaced around the cape and used to

mark positions of the sun at its northern (*Hanakaulua* [Gemini]) and southern (*Kanono*, unidentified) limits.

The name Kumukahi (First Foundation) given to the easternmost point of land in the Hawaiian group is associated with the migration of Mo'ikeha from Tahiti. His younger brother, Kumukahi, got off the canoe near the place bearing his name, while Mo'ikeha continued northward. Several others jumped ship between Hawaii and Kaua'i, and Mo'ikeha pressed onward with his companion, La'amaomao, who had the wind calabash (*Ipu makani a La'amaomao*). La'amaomao would call the winds into the *ipu* when they were too strong for the canoe or summoned them forth out of the *ipu* when the sea was dead calm. Yet, when Mo'ikeha sent Kila, his youngest son, to Tahiti to get another son (or nephew), La'amaikahiki, La'amaomao was not in the returning crew doing all of the navigation for Kila.

About four to five centuries later, in the sixteenth to twentieth generation after Mo'ikeha, his mother, La'amaomao-wahine, bequeathed the wind calabash of La'amaomao to Ku-a-Paka'a:

When La'amaomao finished talking, she opened the cover of a large gourd (*ipu nui*) and drew out a certain small gourd (*ipu hokeo* 'u'uku) which had been woven tightly with 'ie (Freycinetia) cord with a cover (*po'i*) on top.

Then she turned to her son: "I give this gourd to you, as its name was your grandmother's name and mine also, and within it are her bones. When she was alive, all of the winds of this archipelago were her servants, beneath a marvelous power which she received, and she gathered all of the winds into this gourd, and they are still in this gourd until now, and their names were committed to her memory, those from Hawaii to Ka'ula, and when there was no wind, she would remove the cover and call the wind, and the wind would then blow, and when the cover was replaced the wind would cease, and this gourd was famous as the 'Wind Calabash of La'amaomao'." (Nakuina n.d.).

The account of the wind calabash of La'amaomao finds a parallel in the Rarotongan tradition of the wind god, Raka-maomao, whereas in Samoa La'amaomao was a war god. In the tradition of Rata, the wizard Nganahoa combats the demons of the sea in a floating calabash called a "red gourd" (*'ue kura*) from which

he divines their approach and continues to warn the doubting Rata. Nganahoa, a wizard who flies kites, applies to Rata to go with him on his voyaging canoe to find Vahieroa. Rata considers him useless and leaves without him, but Nganahoa follows him on a large gourd floating on the sea:

At the time that the canoe sailed away there were only eleven men on board. The canoe sailed on until the land was out of sight, when the crew descried a large gourd floating on the surface of the sea. The crew threw Ngana'oa and his gourd overboard, and left him to his fate (as they thought).

...The canoe proceeded on its voyage, and had sailed on for some distance when the crew noticed another gourd floating on the ocean; they at once cried out, 'There is our 'ue-kura floating on the sea.' Rata heard them and called out, 'Pick it up.' They did so, and when they opened it they were again confronted by the glistening eyes of Nganahoa. (Nakuina, 1910)

Nganahoa in this form is the bailing calabash, like Hina-ke-ka. In the Tuamotus, Nganahoa is a star represented in Rarotonga as a character prominent in the Rata story. Like Tahaki (Kaha'i), Rata (Laka), grandson of Tahaki, goes on a voyage to find his father, Vahieroa (Wahieloa).

In Hawaii, Nganahoa is the name of the phallic rock on Moloka'i, Ka Ule o Nanahoa (Penis of Nanahoa). This ule was Ul or Uun "Aldebaran" (Hyades, in Taurus) in Micronesian star names. Aldebaran was one of the "four royal stars" or "Guardians of the Sky" in Persian astronomy, 5,000 years ago, when it marked the vernal equinox (Allen, 1963, pp. 383–385).

A peculiar attribute of Nganahoa in the Rarotongan version is that when the bailing calabash was brought aboard the canoe, all that was seen inside were the staring eyes of the wizard. In the Ipu-makani-a-La'amaomao carried by Mo'ikeha on his journey, La'amaomao was, apparently, not a body on the canoe, but rather, the bones of an ancestor in the calabash by which Mo'ikeha called the winds to come out when the ocean was dead calm, calling them back when the winds were too strong.

Aldebaran (Nganahoa, Ka Ule o Nanahoa, Ul, Uun) in Taurus has been an ancient ancestor of star-worshipping wind-watchers on deserts as

well as oceans. That the gourd was encased in basketry in Hawaii is clear in the case of the wind calabash of La'amaomao, but the Unu o Lono shrine, as the Ipu o Lono god image in the hale mua men's eating house, was suspended from a net (koko), reminiscent of the net ('upena) that went across the sky in the Kaha'i story.

Often ignored but present in the tradition of the Ipu o Lono is a small note, "This image had suspended from its neck a gourd, ipu, which was perforated to receive a wooden bail" (Malo, 1950, p. 88). This means that the larger gourd of Lono, the *unu* (temple), also carried the *ka* bailing cup, gourd symbol of the goddess Hina-ke-ka, canoe-bailer form of the moon (goddess) (Johnson, 1989, p. 50).

The Ipu-makani-a-La'amaomao wind calabash is, in part, derived from the Malay word for 'compass', *mata angin*, 'eye of the wind' (*angin*). The standard Polynesian wind compass had eight 'eyes' (*maka*) or as many as 32 wind directions ('Aitutaki, Cook Islands). Hina-ke-ka, the bailing gourd, was not the wind compass (Ipu-makani-a-La'-amaomao). It was a reflecting mirror or an instrument used as a plumb bob or water level. The Nganahoa calabash carried by Rata (Laka) was thrown out into the sea ahead of the canoe.

If Rigi was the Milky Way in the Caroline Islands (Micronesia) whose worm body became the "Eyes of the Pleiades" (Mata-riki, Makali'i) and was the companion (*hoa*) of Rigi, Aldebaran? After the Pleiades sets, Aldebaran is right behind it all of the time. When the Pleiades rise, Aldebaran is right behind them again. It was called "The Follower" (Al Dabaran), i.e., of the Pleiades, originally given to the entire group of the Hyades (Allen, 1963, pp. 383–384). This composed the letter A as the *alpha* in the alphabet derived from the head of the bull consisting of Aldebaran as the eye in the face and the other stars above the head constituting the horns. This eye was the Ule o Nanahoa (Nganahoa) in the wind calabash of La'amaomao (Hawai'i) that had helped Rata sail his canoe in the lands between Samoa, Tonga, and probably, Rarotonga where the tradition is prominently remembered as it is in Hawai'i.

The sky was a place to picture the characters and creatures in the heroic Polynesian past. The major figure was the culture hero and demigod

Maui-ki'iki'i-a-Kalana whose position in the stars favored the constellations of Hercules, Ophiucus beneath, and Sagittarius in the ecliptic to the south. Available to Maui in that hour circle and the adjoining one is the constellation of Scorpius, with which the hero pulled up the land of Hawai'i as a giant fish. Scorpius is pictured as the fishhook that Maui used (Ka makau nui o Maui), three stars lying from east to west above the bright star and mid-shank of the hook, Antares, first magnitude star in the fishhook constellation as it curves around Shaula (Mohalu) to Leshaa in the barb. From the city of Honolulu this "hook" rises over the crater of Diamond Head to the southeast and drags over the sky until it sets to the west. Maui in Hercules sets before the hook ascends, 180° away on the eastern horizon, or a composition of Maui's three brothers, Maui-mua, Maui-roto, and Maui-pae, who are the three stars in the Belt of Orion stretched over 10° on either side of the equator. They are pictured as sitting in a canoe as they are helping Maui to pull together the fish that Maui caught and which drifted into separate parts. They were told not to look back, and as one of the three brothers does look back, the fish comes apart again into separate islands. Otherwise they are three men in a boat in a canoe house straddling the equator. Beside the Belt of Orion in the place of his sword, the ancient Hawaiians evidently saw the same shape of a weapon, calling it Na Kao, the javelins, i.e., the Belt and Sword of Orion, or perhaps they mistook it for Na Ka o Makali'i, the bailers (i.e., bailing gourds) of Makali'i (in the Pleiades).

Another interesting facet of Scorpius is that it lies within the swirling, twisting motion of a stream or pond of water, the Milky Way, as it courses or spirals across the sky during its own moving about. It will be seen stretched across the sky as a diagonal, from northeast to southwest, and only certain stars and constellations lie in the stream, called the Wai Ola a Kane, or living waters of Kane, the creator-god. In the same stream lies a reptile or shark called 'Ai-kanaka, whose wife is the moon, Hina-hanai-aka-malama. Through the year the lizard or reptile will jackknife across the overhead skies as

the swirling stream moves until it is lying from northwest to southeast. Then it lies in two separate streams across the north and across the south, and then arches around the entire visible horizon before it slips off the edge of the world and comes back again, spiraling across the sky from northeast to southwest.

This is the galaxy, and the center around which it spirals is the galactic equator, and by it the ancient priesthood also told time. The motion of breaking up of the spiral was called *Kaha'i*, *Ha'iha'i*, *Ha'imoha'i*, for another hero of the migrations, Kaha'i, who went to the skies on a rainbow to look for his missing father, Hema. Only certain stars and constellations are found in the *Wai Ola*, pictured also as a coconut tree, with branches opening to the north and the roots growing to the south. Sirius lies outside this swirl, seeming to be alone and thus called, Lono-meha, "Lone Lono." Another star that seems to shine alone and brightly to the north is Arcturus in Bootes, called Hokule'a, meaning "clear star" or "star of gladness," according to the Polynesian Voyaging Society which named the canoe after Arcturus.

Otherwise, the Milky Way was called the "spine," *Kuamo'o*, in which the following were always found: Castor and Pollux in Gemini, called the "Twins"; Mahana Kaulua, or Na Mahoe, the twin in front, Castor, Mahoe Mua, and the twin behind, Pollux; Mahoe Hope; the Hyades, Kaomaaiku or Kanukuokapuahi; the Magellanic Clouds, "butterflies," Pulelehuakea, Pulelehualei; stars in Lyra, Keoea, Keho'oea, and Scorpius.

In the opposite pole, Canopus was called the solitary "Lord of Space," Ali'i-o-Kona-i-kalewa. It occupies the pole at one time, the star Achernar at another, and then there is the Southern Cross, rising on its side in the east, then coming upright, before tilting to the west and going out of sight. Some Hawaiians see a triggerfish, *Humu*, as the *humuhumu-nukunuku-a-pua'a*, or pig-snout fish in which the pig demigod, Kamapua'a, made his journeys by sea assuming the form of a triggerfish. The snout of the fish is pointed downward and the fin upward. Others knew the Southern Cross as a "cross" Hoku Ke'a, or a batfish, one of the skates or rayfish

with wings outspread, tail upward, guilty for stealing the moon and hiding her, mother of culture hero Maui-ki'iki'i-a-kalana. So Maui retrieved Hina from the clutches of the batfish by waiting for the demon fish to close all of its eight eyes in sleep before he cut all of them out of the head of the monster. Another *humu* star, meaning, to be sewn or patched together, *humu*, is Humu, or Altair in Aquila, west of Maui-ki'iki'i-a-kalana. The pole star to the north, Polaris, is called Hokupa'a, "Fixed Star," but then all stars fixed in their tracks were called *na hoku pa'a* as against "wandering stars" or planets, the *hoku ae'a*, "wandering" or "vagabond" stars. The whole constellation of the Big Dipper was called "The Seven," Na Hiku.

Below the pole starting with Perseus is a line of stars that meets up with the asterism of the Pleiades in the head of the Bull, Taurus. These stars are called *a line*, i.e., Ka Lalani. Near the Pleiades, called "Little Eyes", Makali'i, are the Hyades, which are the opening of the fireplace, *Ka Nuku o Kapuahi*, recalling perhaps, as on the island of Mangaia in the Cook group, that a tribe of people suffered being cooked alive in an oven. Aldebaran in the eye of the Bull is called *Ka Oma Aiku*, meaning the adze of Aiku, one of the heroes of the migrations in the south, also known as Aukele-nui-Aiku, a navigator who found the home of Pele's sister in Ra'iatea and Borabora. The other "twins," Mahapili, are in Scorpius. The orbit of the stars was called the "circular road," *Ala Poai*. For the most part, so many star names retained in the nomenclature are unidentified, indicating the loss of much that the ancients had identified about the sky concerning the heroic past of their own wanderings, as they often called it, to go over the horizon ever receding.

Muku	0	"cut-off"	New moon, dark phase
Hilo	1	"braid"	Moon in the west
Hoaka	2	"tusk" (moon shadow, boar tusk)	

(continued)

Ku-kahi	3	Ku-1 "cusp" (moon going south)	
Ku-lua	4	Ku-2	
Ku-kolu	5	Ku-3	
Ku-pau	6	Ku-end	
'Ole-ku-kahi	7	'Ole-1 "eye-tooth" (moon in the south)	
'Ole-ku-lua	8	'Ole-2	No planting nights
'Ole-ku-kolu	9	'Ole-3	Moon southeast
'Ole-pau	10	'Ole-end = one <i>anahulu</i> decan week of 10 days	

Huna	11	"hidden" as cusps of the moon
Mohalu	12	Shaula, in Scorpius
Hua	13	Jupiter = one-half sidereal lunation
Akua	14	God (moon in the east)
Hoku	15	Star (full moon)
Mahealani	16	16th moon (full moon)
Kulu	17	"drop" (waning moon)
La'aukukahi	18	"plant" 1 (moon going north)
La'aukulua	19	"plant" 2
La'aupau	20	"plant end" = two <i>anahulu</i> decan weeks
'Ole-ku-kahi	21	'Ole-1 (quarter moon, north)
'Ole-ku-lua	22	'Ole-2
'Ole-pau	23	'Ole-end
Kaloa-ku-kahi	24	Ka(na)loa 1 "god of the sea" (fishing)
Kaloa-ku-lua	25	Ka(na)loa 2
Kaloa-pau	26	Ka(na)loa-end
Kane	27	Milky Way = one sidereal lunation
Lono	28	Lono (moon west of north)
Mauli	29	"spirit"
Muku	30	"cut-off" = three <i>anahulu</i> decan weeks
		=one synodic lunation

(1) Tabu pule of Ku	2 1/2 nights	Hilo, Hoaka, Kukahi, Kulua
(2) Tabu pule of Hua	1 1/2 nights	Mohalu, Hua, Akua
(3) Tabu pule of Kanaloa	1 1/2 nights	Olepau, Kaloakukahi, and Kaloakulua
(4) Tabu pule of Kane	1 1/2 nights	Kane, Lono, Maui

Astronomy in Japan: A Cultural History

Steven L. Renshaw

Center for Asian and Pacific Studies, University of Iowa, Iowa, USA

Japan's astronomical heritage, like so much of the culture's history, is one of enigma. Navigationally remote in ancient times and perhaps somewhat still socially remote amidst modern urbanization, it is easy for native and foreigner alike to perceive that there must be something unique and mysterious about what is "Japanese." Yet, this island country is a mixture of Eastern and Western imports, and the social, political, and pragmatic processes related to such importation have origins dating back at least two millennia. One who actually visits the country may be somewhat overwhelmed

by a large number of temples, shrines, and other architectural landmarks, some dating back many centuries, all reflecting an interaction of native sociocultural systems with those derived from the Asian continent. The visitor may also be somewhat disappointed to find much of the nation's heritage engulfed by high-rise buildings and accompanying elements of industrialization, a factor which is also very much a part of modern Japan. Illumination from such industrialization is a thorn to every lover of the stars, from amateur to professional. Perhaps it is indeed the mixture of foreign imports with indigenous belief systems, a mixture more subtle than that of cultures such as the United States whose multiethnicity is so pronounced, that indeed proves to be the most unique aspect of Japan. In order to understand the deeper significance of Japan's heritage with the sky, one must often look beneath what appears on the surface.

For many in the West, astronomy in Japan is generally connected to Japanese names attached to comets, asteroids, and supernova discovered by one of her many amateur astronomers, to astronauts accompanying NASA missions, to space probes launched from Tanegashima Island, or to the building of a huge telescope on Mauna Kea sporting the name of one of the most prominent asterisms of Japanese star lore, *Subaru*. A complete review of issues related to this heritage is far beyond the bounds of a single article. We will concentrate primarily on the cultural relations with the stars that have developed over the centuries in Japan. To provide an overview as well as a basis for understanding what astronomy means to this land, we will concern ourselves with (1) the development (or perhaps nondevelopment) of astronomy as a science in Japan and (2) the significance of historical, social, and political purposes and their relation to star lore, mythology, and other aspects of cultural astronomy.

Astronomy as Science in Japan: Chinese and Western Influences

Many professional and amateur astronomers in Japan have asked, "Were ancient Japanese people

not interested in the stars?" (e.g., see Yokoo, 1997). Such a question reflects the fact that compared with Western traditions, it is quite difficult to find early star mythology and records of scientific or prescientific development that compare with many other ancient cultures. Though the exact date is uncertain, writing was introduced relatively late to the Japanese islands (the system was based on Chinese characters), and thus there is very little written record of ancient views of astronomy earlier than the seventh or eighth century.

In looking at Japan's development of astronomy, Aveni's (1989) allusion to a kind of ethnocentrism inherent in viewing *History of Astronomy* only through the eyes of the modern West and its evolved science is echoed in reverse. The Meiji Reformation (1867–1868) with a "de-emphasis" of Buddhist traditions followed by post-World War II rejection of the most meaningful aspects of indigenous Japanese mythology left many in this country with a sense that there is and always has been little which can be considered original in astronomy emerging from Japan. On the other hand, the reader needs only to pick up any professional journal of astronomy to quickly find the names of Japanese authors who are conducting research in the science of astronomy using Western methodologies. Thus, to look at modern astronomy in Japan is not to look at any real cultural difference but instead to find an industrial country which is producing an increasing number of eminent scientists trained in Western methodologies. The importance of understanding cultural context relative to astronomical "knowledge" has been recently revived, and one cannot help but sense a certain "lack of self-esteem" among Japanese researchers who wish to pursue it.

In his *History of Japanese Astronomy*, Nakayama (1969) gives a very thorough account of the ways in which Chinese and later Western influences were imported into Japan throughout its history. Japanese astronomy was greatly conditioned and restricted by geographical, historical, and cultural barriers, and its early phases were dominated by Chinese influence and later by Western ideas. It is doubtful that any

"scientific" expansion of Japanese astronomy occurred prior to close contact with China or with China via Korea. Further, while the primary purpose of calendrical study both in the West and in China was to develop precise means of time reckoning, calendar development in Japan generally focused on divination and securing the position of rulers rather than trying to develop precise theory, cosmology, or observation methods designed to explain the workings of the universe.

Nakayama's work is written in English and parallels the two-volume work on the *History of Astronomy* in Japan written in Japanese by the esteemed scientist and historian Watanabe (1986, 1987). A view of most Western discussions of the subject will lead the reader to conclude that little has changed in perception relative to Nakayama's assessment (e.g., see Hashimoto, 1997; North, 1995; Pannekoek, 1961; Ronan, 1996; Sugimoto & Swain, 1989). While Aveni (1993) does emphasize more ethnographic and less ethnocentric viewpoints, he also tends to place Japan within the broader context of the "rich Chinese heritage" and does not really deal with Japan's cultural astronomical heritage.

When the English scholar, Chamberlain (1971), was assessing the general state of affairs in Japan in his *Japanese Things*, he indicated that even apart from any scientific originality, one would never find much creative lore composed in Japan relative to the stars. Viewing astronomy in Japan from only these perspectives, it is easy to get the impression that early and perhaps even later inhabitants of Japan who never "looked up" were never inspired by much in the sky, patiently and/or eagerly waited for (or perhaps at times were even antagonistic toward) enlightenment from the Asian continent or later from the West, but nevertheless developed keen observational skills once such imports were implanted.

It is certainly true that almost everything which can be viewed as scientific astronomy was imported from the Asian continent or from the West in more modern times, and if only that side is viewed, discussion of the *History of Astronomy* in Japan can basically stop here. However, to discard the culture's relations with the sky by judging it only by its origination or

development of scientific concepts dismisses what is perhaps one of the most unique case studies in how indigenous native beliefs (and accompanying views of the heavens) were integrated, seldom by forceful means (at least from the importer's side), with belief systems of other cultures (and their consequent views of the heavens). Such a pattern of coexistence has been paradoxical if not downright baffling to most Western eyes. By neglecting the sociocultural side of Japanese history, one misses the complexity of the manner in which ancient Japanese (not only rulers, astrologers, and calendar scholars but average farmers, fishermen, and other common citizens) incorporated astronomy into an extant system of belief and purpose, such providing culturally based reasons for the way astronomy did or did not develop in these islands.

Although we discuss many other examples of Japanese adaptation and development in the next section, it is worth noting particular historical events that we have explicated elsewhere (Renshaw & Ihara, 1999). Consider the large influx of Chinese learning in the Asuka (late sixth to early eighth centuries AD) and Nara (710–784 AD) periods. (An exhaustive account of these periods and the influence of continental imports are far beyond the scope of this article. The reader may find articles from Vol. I of *The Cambridge History of Japan* series including Brown (1993a, b, c), Kidder (1993), Inoue (1993), Naoki (1993), Matsumae (1993), and Sonoda (1993) to be particularly relevant to a deeper understanding of these processes.) Certainly, palaces and Buddhist temples were being laid out using Chinese-derived geomantic principles, and Chinese methods of calendar reckoning were adopted (Nakayama, 1969). However, each aspect of Chinese learning that was incorporated had to find juxtaposition with a set of beliefs or purposes that sometimes stood in direct contradiction. Juxtaposing the descendancy of the emperor as a child of the sun goddess Amaterasu with the Chinese perception of imperial rule centered on the north celestial pole required some compromise. Buddhist temples aligned in north–south directions had to fit within a terrain

that had Shinto shrines aligned in less celestial fashion but more along the flow of natural sites such as prominent sacred mountains, forests, waterfalls, or distinguished outcroppings of rocks. Apart from the necessary attendant “blessing” of a particular Shinto deity on a Buddhist temple, the said deity often had a shrine built directly within the precincts of the temple grounds and was even given a form of “Buddhahood.” Compromises also included such practices as substituting Shinto ritual objects for bones of the Buddha in the treasures buried beneath pagodas (see Brown, 1993c; Matsumae, 1993; Sonoda, 1993).

The picture we see from reading Krupp (1983, 1989) substantive accounts of temple layout and practice of seasonally based ritual in ancient Chinese capitals was only partially incorporated within the layouts and attendant rituals of ancient Japanese palaces and their imperial owners. Certainly, as will be seen in the review of social consciousness and purpose in the next section, rituals such as human sacrifice found no place in a belief system based on ritual purification and abhorrence of death. It is also significant to note that while China underwent several dynastic changes, some accompanied with revisions in cosmology and astronomical perception, Japan retained virtually one dynastic descendancy reaching well into the twentieth century, thus often seeing no need for “advances” taking place on the continent (Brown, 1993a, c).

When cultural perspectives are included, it seems clear that the history of Japanese astronomy is not simply the history of Chinese astronomy or even, for better or worse, a direct mirror of such. While it may be impossible to distinguish anything as having been uniquely Japanese, cultural practices from earliest to modern times bear distinct marks of a social consciousness and purpose inherent in Japan's cultural development. Too, while Chinese astronomy may not have been given its due in modern scholarship, it is also evident that all Asian cultures cannot be “lumped together” with China in order to gain a full understanding of the relation of astronomy and culture in any particular one.

Socio-Political Purposes and Their Impact on Development and Adaptation of Star Lore and Mythology

Ruggles and Saunders (1993) ask, “What do people see when they look at the sky?,” and further state that the answer is as much a cultural as an astronomical one. Their perception is especially relevant to unraveling the enigma of Japan’s heritage with the sky. A growing database of archaeological evidence, renewed postwar and nonreactive scholarship with regard to historical texts, and the development of interdisciplinary approaches reveal Japan as a culture that has always been guided by an indigenous social consciousness and for most of its history a rather consistent set of social and political purposes (Brown, 1993a). Such was certainly a factor in how Japanese developed myth, legend, and lore related to the stars, and it is in this area that we can find the rich sources of cultural astronomy in Japan. (A good chronology in English of Japan’s general history may be found in Torao and Brown’s (1991) *Chronology of Japan*. The most exhaustive history of Japan in English is the recently released Cambridge series (Hall et al., 1993). For shorter and perhaps more approachable views of Japanese history written in English, the following may be of value: Sansom’s (1974) prewar but still viable 3-volume *A History of Japan* and his (1973) *Japan: A Short Cultural History*; Hall’s (1971) *Japan From Prehistory to Modern Times*; Mason and Caiger’s (1973) *A History of Japan*; and Morton’s (1995) *Japan: Its History and Culture*.)

The ancient sense of social consciousness and purpose may best be understood by using the analogy of a lake fed by two springs. The lake represents the historical and modern sociocultural milieu of Japan, and the springs feeding it are the sources from which that milieu has been formed. The first and nearest spring is composed of a native social consciousness and a specific set of socio-political purposes that we detail later. The second spring (better viewed as many secondary springs) consists of the infusion of ideas, concepts, technologies, philosophies, and religions including a virtually continuous input

from the Asian continent and in later centuries large contributions from the West.

It is important to realize that the primary spring has always been fed by the second. The flow may have been slow or even imperceptible at times, but it has always been there (Oguma, 1995). On the other hand, this primary spring (regardless of its diverse historic origins) has always been deep and has formed an archetypal base through which everything must be filtered to become “Japanese.” At least within the last 1,600–1,800 years, the secondary spring has probably never had a direct route to Japan’s archetypal lake; such flow has almost always passed through the primary spring.

Brown (1993c), Kidder (1993), and Matsumae (1993) have provided a cogent paradigm through which Japanese social consciousness and attendant Shinto beliefs and practices may be understood as well as socio-political purposes that guided the early formation of Japan as a unified country. From this paradigm, three primary aspects of early Japanese consciousness emerge: “linealism,” “vitalism,” and “optimism.” Linealism emphasizes ancestral descendancy with filial duty to parents, siblings, friends, nation, etc. Vitalism emphasizes life along with the abhorrence of anything that has to do with death and stresses ritualistic (not moralistic) purity. Optimism places emphasis on being concerned, not so much with the distant past or future but rather with moving forward through seasons and cycles of life, regardless of circumstances. The socio-political purposes which played a role in Japan’s early development as a nation may perhaps be best paraphrased as follows: (1) unification of often warring petty “kingdoms” (along with their local myth, legend, and lore) through (2) cooperative efforts of common people in various ways such as cultivating rice (using celestial signs and allegories for seasonal determination of planting and harvesting as well as agriculturally based festivals) in order to (3) establish a singular lineal order of imperial rule (resulting in perhaps one of the greatest national Japanese myths that of the sun goddess Amaterasu and her place as ancestral head of the imperial line). (From our earlier discussion, the

reader should have a good idea of the kinds of conflicts many imported ideas created for early Japanese. Other brief examples will further clarify the point: while the infusion of Confucianism reinforced many aspects of “lineality,” especially with regard to the development of bureaucratic governmental practices, the Confucian idea of a cyclical rise and fall of dynasties was never really accepted in Japan and stood directly against the idea of a singular imperial line. The fourth- and fifth-century infusions of Buddhism with beliefs, which emphasized a better life in death than in the present, directly contradicted the concept of vitalism and optimism. In addition, the Buddhist idea of eventual decay and the Confucian idea of a “glorious past” were incongruent with virtually all aspects of Japanese consciousness and purpose.) It can easily be argued, given the political developments of the twentieth century, that while some commodities have changed and political power has not always been imperial based, these fundamental aspects of Japanese consciousness and purpose still form a prime keystone of the culture’s psyche. (It is easy for the reader to get full insight into the significance of these ideas by reading the many excerpts of manuscripts from periods throughout Japan’s history which are accompanied by commentary in the excellent *Sources of Japanese Tradition* compiled by Tsunoda, de Bary, and Keene (1964). The sense of Shinto consciousness and its pervasiveness in modern Japanese life is also discussed by Shigemitsu (1996).)

One of the few writers in English to deal with Japan’s cultural star lore and myth is Krupp (1991, 1997). Readers may be familiar with the several accounts he provides of the fundamental Japanese myth of Amaterasu and its relation to the Japanese political history. However, while this myth, itself closely tied with the political purpose of unification, is a prime example of lore that reflects Japanese sense of consciousness and purpose, there are many other aspects of Japanese traditions and bodies of star lore which show the complex relation between indigenous native belief, pragmatic social need and purpose, and the kinds of celestial ascriptions that developed therefrom. Little of this material

has found its way into English sources, and in the remainder of this article, we discuss some of the many examples of relations between Japanese values and social purpose and the stars. Specifically, we will look at (1) values applied to particular star groupings such as Oyaninai Boshi; (2) cooperative efforts such as planting, harvesting, and fishing reflected in star lore closely tied to such asterisms as Subaru and the belt stars of Orion; (3) ancient Japanese purposes as seen in star paintings of archaeological sites such as the tombs of Takamatsu Zuka and *Kitora Kofun*; (4) mixtures of Shinto belief and values seen in adaptations of continental legend and ritual such as that of the legend of Orihime and Kengyuu and its relation to the festival of Tanabata; and (5) the preeminent holiday of the year for Japanese, New Year’s Day, in which the values of linealism, vitalism, and optimism come together in a celestial greeting of new beginnings.

Oyaninai Boshi: Linealism, Vitalism, and Optimism in the Stars

There are a number of celestial symbols which concern various groupings of three stars: Oyaninai Boshi including Orion’s belt stars (Nojiri, 1973), three stars of the fifth moon station of the Azure Dragon of Spring which includes Alpha Scorpio flanked by Sigma and Tau, and three stars discerned in the constellation Aquila including Alpha flanked by Beta and Gamma Aquila (Uchida, 1973). (Here and in later sections, we discuss the Chinese-derived *Sei Shuku* or “moon stations” along with the animals of cardinal directions. Though used extensively in Japan from earliest Chinese infusions, a discussion of their complexity is more appropriate in a work on Chinese astronomy. The reader is urged to look at sources such as Needham (1959), Ho (1985), or Nivison (1989).) All have to do with seeing the image of two parents standing or being supported on either side by their child in the middle. Such symbols of filial duty are numerous in Japanese star lore and reflect the strong sense of lineality later reinforced by Confucian ethics. Further, particular attention is

placed on this value relative not only to parents but to friends as well. An example of a sense of Japanese identity is seen in Kenji Miyazawa's more modern "lore," the *Milky Way Railroad* (Sigrist & Stroud, 1995). (*Douwa Shu; Ginga Tetsudou no Yoru* (A Collection of Tales; Night of the Milky Way Railroad) was originally started in 1924, adapted for some years, and finally published posthumously in 1951 (Miyazawa, 1951). It remains one of the most popular stories in Japan, loved by children and adults.)

Another legend incorporating the aforementioned sense of Japanese consciousness includes the belt stars and M42 region of Orion. According to Uchida (1973), one day, two sisters were walking down the road, the younger dutifully following her older sister and shouldering a tub of water. Being chased by an ogre, they found a rope leading to the heavens and began to climb. Though the sisters escaped the ogre, the younger sister sadly had her foot bitten off. These days, we see the bamboo pole (the three belt stars called Take no Fushi in this story) with which she continues to carry water as she follows her sister (the moon) around the sky. Her remaining foot (M42 region) peeks from the folds of her kimono. Western readers may find the end of this legend disturbing or even somewhat cruel. However, all the fundamental values of Japanese consciousness are found in this story: linealism in the form of filial duty, vitalism in strength and courage, and optimism in a will to "go on" within one's present condition to an immediate brighter future.

The anecdotal nature of such star lore and legend takes on a completely different meaning when viewed within the context of ancient Japanese social consciousness and purpose. Again, while it would be futile to argue that such lore developed independent of external sources, it is also clear that its Japanese development reflects a unique cultural identity.

Cooperative Activity: Pragmatic Signs in the Stars

As in many cultures, the three belt stars of Orion (called *Mitsu Boshi*), the Hyades (*Ame Furi Boshi*)

or rain stars), and the Pleiades (*Subaru*) played a prime role as symbols of fertility and timepieces relative to seasonal change, specifically planting and harvesting during the rice cultivation period (1982; Hirose, 1972; Nojiri, 1973, Uchida, 1973). Their earlier and later heliacal setting in spring as well as heliacal and later rising in fall encapsulate that season and in more ancient times provided symbols related to festivals such as Spring *Higan* and *Ura Bon*. Spring *Higan* is celebrated within a period of 7 days surrounding the spring equinox. At this time, as any casual observer in latitudes similar to Japan will note, the Pleiades, Hyades, and Orion, all begin to set earlier and earlier each evening. For early Japanese, this setting was allegorical to planting of rice seedlings (*Subaru* or the Pleiades appearing as united seedlings), the rainy season (Hyades or *Ame Furi Boshi* seen as rain stars), and cultivation (one of the earliest symbols seen in the three belt stars of Orion was that of *karasuki* or plow). *Ura Bon* is celebrated in the fall when ancestral *kami* (deity) visits and is sent on their way in thanks for bountiful harvests. In more ancient times, when this festival was celebrated on the lunar calendar-based 14th–16th days of the 7th month (late August or early September in the Gregorian calendar), these three prominent star patterns were indeed seen to transit the zenith as the full moon set and dawn arrived, a signal that ancestral spirits had indeed departed for yet another "season" (Miyata, 1996). The appearance of *Subaru* rising in the evening at this time of the year seems to have had significance not only in its relation to the end of the rice harvest but to the coming of winter.

The mythology found in the *Kojiki* (Records of Ancient Matters; see Chamberlain, 1981; Philippi, 1968) and the *Nihongi* (Chronicles of Japan; see Aston 1972) places much importance on the deity (sun goddess) *Amaterasu*, who "conquered" lesser deities (local states) and was considered the progenitor of the imperial line. Interestingly, one of the earliest and most significant aspects of *Subaru* was related to the myth of *Amaterasu*. Apparently taken from the phrase *mi Sumaru no Tama*, the name *Sumaru* was used to describe this asterism referring to the string of the

August jewels known to have been hung on the *sakaki* tree while deities danced to lure Amaterasu from the cave (Nojiri, 1973). Allegorically, just as the sun (Amaterasu) was seen to depart for the winter, jewels (Subaru or Sumaru) were seen to appear in the sky, jewels which could be seen throughout the winter months and serve as a reminder for early Japanese that at some time the sun would indeed return with her spring warmth and another planting season could begin.

Lore related to Subaru is extensive, but its prime importance can be seen in the fact that it not only played a role in what would become a central myth for unification of the country but also a timepiece for the pragmatic need of farmers and fishermen who played a role in such unification efforts. For common people, struggle for unification was of secondary importance. What was of prime concern was that they know good and bad times for planting, harvesting, or setting lines for fishing. While the three star patterns we have mentioned were of significance because of their heliacal rising and setting, the three belt stars of Orion, due to their prominence, apparent equal spacing, and perceived change in position as they traced their way across the winter sky, were of particular pragmatic use to early and later Japanese citizens.

When viewed in early evening, the perceived angle of the three belt stars, seen rising in the east, moving across the sky, and setting in the west at different times of the year, provided the base for particularly interesting lore in which farmers used Orion as an agricultural symbol (Hara, 1975; Nojiri, 1988; Uchida, 1973). The three belt stars are variously called *Awainya Boshi* (Millet Stars), *Komeinya Boshi* (Rice Stars), or *Awaine Boshi* (Millet and Rice Stars). All these names relate to seeing *Mitsu Boshi* as a fulcrum, balancing the yield of rice or millet crops as they move across the heavens. The star *Alnilam* (*Epsilon Ori*) is seen as the center of this fulcrum. *Mintaka* (*Delta Ori*) being higher or lower than the center indicates the yield of millet; *Alnitak* (*Zeta Ori*) represents the yield of rice. In latitudes of Japan, *Mitsu Boshi* rises in an apparent vertical position. As the three stars move across the sky in

the fall, they appear at an angle that gives rice a strong weight on the balance; this is the time to harvest rice and plant millet. As this constellation is seen setting in the West in late spring, Zeta Ori begins to dip lower and lower; this is the time to harvest millet and plant rice.

Especially in the cultivation of rice, several symbols of agriculture have been seen in the relation of the three belt stars to the M42 region. One of the oldest object references associated with this configuration uses the term *karasuki* to describe the three belt stars as prongs of a plow with the M42 region being the handle used to pull it in the field. As mentioned earlier, this symbol is especially meaningful related to the evening appearance of the three stars in the time of early spring.

As a further example of adaptation of imports to suit unique and indigenous Japanese needs, it is interesting to look at some of the Chinese interpretations of star groupings such as Subaru or the three stars of Orion's belt and the differences in names applied by each culture. By the seventh century (perhaps earlier), the Chinese "cosmology" which gave rise to the concepts of 28 *Sei Shuku* or lunar stations encircling the celestial globe had found its place in Japan (Nakayama, 1969; Watanabe, 1987). The constellation of Orion contains two such *Sei Shuku*: the 20th which includes the small *Meissa* (*Lambda, Phi Ori*) and the 21st which embodies a much larger section of Orion and is most distinguished by the belt stars (*Mitsu Boshi*). Chinese characters were used by later Japanese writers to represent these configurations; however, the original Chinese term for the 21st *Sei Shuku* was simply *Shin* (three) while earliest records of Japanese nomenclature use *karasuki* or plow (Ozaki et al., 1993; Shinmura, 1994). Early Japanese gave little significance to the 20th station. Though continental influence can certainly not be dismissed as a major factor in Japan's agricultural development especially with regard to tools, it would appear that seeing this agricultural symbol in Orion may indeed have been in use before introduction of writing and other imports of more advanced Chinese culture into Japan.

Following massive infusions of culture from China and Korea, Japanese emperors practiced the custom of “plowing the first furrow” around the lunar New Year. However, Japanese lore associating the three stars with a plow seems to have preceded and perhaps only been augmented by the introduction of this Chinese-based ritual. See Krupp (1983, 1989) for a description in English of this and other cultivation-related ceremonies that were practiced by the emperor in China. As they were recognized in Japan, some became part of the imperial ceremony, but many never found a place either because they did not fit within the imperial “purposes” mentioned earlier or because they were in direct conflict with native *Shinto* belief (e.g., ritual sacrifice.) “Astronomy” as practiced in China during Japan’s early formation as a nation had depended for some time on somewhat more precise estimates of a lunar calendar for fixing dates (Ho, 1985; Nakayama, 1969). Because of its pragmatic use as an agricultural sign (though nonprecise), especially its prominent evening setting at what later was called Spring *Doyou* (the period of 18 days prior to the sectional term “Summer Begins,” the official time for preparation to begin planting rice), *karasuki* may have been original with early Japanese farmers. At any rate, its setting has certainly survived as a symbol of planting in most rice-producing parts of Japan.

Another symbol for planting indeed reflects Chinese influence, and this is clearly seen in the incorporation of *kanji* or Chinese characters. This symbol, again related to the setting of Orion in the west during the beginning of the rice cultivation season, was yet another reinforcement for use of the belt stars and M42 region as a sign for planting. Uchida (1973) indicates that Japanese in some agricultural areas see the *kanji* for “entry” in the configuration and call it *Hoshi no Iri* (Entry of Stars). As fishermen saw stars set into the sea, Japanese farmers saw stars set into the western landscape. This symbol of *Iri* was merely another sign that it was time to plant (enter) rice seeds into the earth (Fig. 1).

Agricultural associations discussed so far have generally been related to the setting of *Mitsu*

Astronomy in Japan: A Cultural History, Fig. 1 The *kanji* for *Iri* or Entry superimposed on the belt stars and M42 region of Orion (Computer graphic by Steven L. Renshaw)

Boshi during early stages of annual rice cultivation. As mentioned, the rising of the three belt stars in the east was also an agricultural symbol and was allied with the end of the period of rice cultivation. Hara (1975) records that in many rice-farming areas, the stars were called *Haza no Ma*, a term that refers to a three-pole stand that is used in the field to dry rice. In the early phases of autumn, when Orion is no longer seen at sunset but rather rising earlier and earlier each night, farmers looked to the belt stars and saw them as a symbol that “only *Hasa* are left in the field,” the harvest of rice being over.

While the combination of a lunar calendar and later adoption of a Gregorian calendar in post-Meiji era in Japan led to more precise methods for determining times for planting and harvesting, many old farmers in rural agrarian areas still use methods that are centuries if not millennia old. According to Uchida (1973), the following time-piece is still recited in such areas: “When *Mitsu Boshi* are one fathom high, it’s time to go to bed; when *Mitsu Boshi* are in the middle, it’s the middle of winter; and when *Mitsu Boshi* lay, it’s time to wake up.” This refers to the vertical alignment of the three belt stars as they rise in

early fall, the angular position in the middle of the southern sky in winter and the horizontal visual alignment in the west in spring. These metaphors are related to, respectively, fall harvest, winter rest, and spring planting.

Star lore related to fishing is somewhat more rare than that which is related to crop cultivation. It was primarily through cooperation of local farmers along with their local ancestral *kami* in the production of rice that early Japanese rulers were able to fulfill their purpose of unifying the country. Still, incorporating the legends of families of fishermen was an important part of this unification, and a mix of agrarian and fishing lore is found (see Nojiri, 1982, 1987).

In some fishing areas, the three belt stars are called *Kanatsuki*, which is a name given to a spear with three prongs used in fishing (Nojiri, 1973; Uchida, 1973). We can note some similarity in pronunciation of *karasuki* (plow) and *Kanatsuki*. As a sign, *Kanatsuki* was used as a timepiece for favorable catches. When prospects for such seemed to be particularly good in the fall, old fishermen were often heard to say “Let’s wait for *Kanatsuki*” before going out for the evening’s catch.

Perhaps one of the most significant relations to “fishing” found with *Mitsu Boshi* relates to their designation by some fishermen as Sumiyoshi Boshi. Sumiyoshi were the three deities mentioned in the *Kojiki* as being created from the ocean and being particularly favorable to seafarers (Nojiri, 1988). Incorporation of these deities in the *Kojiki* and *Nihongi* was no doubt designed to find favorable reaction from the *be* or local families of fishermen. However, their use in legends which also included allusions to agricultural symbols makes them a significant aspect of the way in which Japanese developed celestial allegories.

Obviously, ancient Japanese were not blankly “staring at their rice fields” while the heavens “revolved” overhead. Creative and pragmatic use of star patterns played a central role in the day to day life of common citizens. Using the example of the belt stars of Orion, we have briefly discussed some of the more significant associations used in cooperative activity.

Adaptation of Asian Cosmology for Power and Centrality: *Takamatsu Zuka* and *Kitora Kofun*

Some archaeological sites may provide cogent information relative to the early interaction of Japanese values and purpose with imported cosmology. One of the major archaeological discoveries was made in the early 1970s (Hirose, 1972) in Asuka village, Nara prefecture. From an Edo era painting showing this mound with a tall pine tree atop, this tomb was called *Takamatsu Zuka Kofun* (Tall Pine Burial Tomb; Fig. 2).

Dating indicates that the tomb was built in the latter part of the seventh or early part of the eighth century. As was and is the case with most burials in China, Korea, and Japan, the tomb was aligned with celestial north. Paintings of animals related to the four cardinal directions were found on the walls, and careful inspection of the ceiling revealed a chart including the 28 *Sei Shuku* (lunar stations). Only a few scholars knew of the tomb’s existence in the Edo era (1603–1867), and most believed it was that of the Emperor Monmu (emperor from 697 to 707). Modern excavation revealed no inscription, and Monmu’s tomb was later determined to be to the east. Similar tombs have been found in both China and Korea, and the construction period was also one in which scholars from Korea had been invited to the imperial court.

What is significant about *Takamatsu Zuka Kofun* is the fact that it clearly shows the influence of Chinese and Korean cosmology on Japan in the Asuka era (late sixth to early eighth centuries). In 1998, another such tomb, located about 1 km to the South of *Takamatsu Zuka Kofun* on Mount Abe and named *Kitora Kofun* (after the Kitaura area of Asuka village), was explored. The tomb was not actually entered but probed with subminiature cameras. Preliminary dating placed its construction within the same Asuka period as *Takamatsu Zuka Kofun*. While there are some remarkable similarities, there are also some anomalous differences in the paintings of the two tombs.

In *Kitora Kofun*, the paintings of the animals of cardinal directions appear to be in somewhat

Astronomy in Japan: A Cultural History,

Fig. 2 *Takamatsu Zuka Kofun* is aligned with celestial north. This view from due south shows the bamboo-covered mound of the tomb. The doors are to chambers of relatively recent origin; inside are housed temperature maintenance and dehumidifying equipment used to protect the small tomb's delicate paintings. The tomb is not opened to the public (Photo by Steven L. Renshaw)

better condition than those of *Takamatsu Zuka Kofun* (in which some paintings appear to have been defaced in ancient times). The animals do seem to have been painted in a freer style than those that are found in the tomb to the north. There also appear to be more stars in the *Kitora* tomb paintings of the *Sei Shuku*. Unlike *Takamatsu Zuka Kofun*, the celestial equator and ecliptic as well as “the heavenly river” or Milky Way appear distinct. Like *Takamatsu Zuka Kofun*, the tomb appears to have been plundered of any “treasure” it may have held. The south wall of *Takamatsu Zuka Kofun* was obliterated by entry in ancient times thus eliminating the painting of the Red Bird of Summer.

With regard to astronomical content, there are other significant differences. First, the paintings of *Sei Shuku* in *Kitora Kofun* appear to be based on Chinese/Korean charts of a much earlier period than that of *Takamatsu Zuka Kofun*. Second, the point of the crossing of the ecliptic with the celestial equator can be seen in *Kitora Kofun* and appears to be near a point in Aries closer to Taurus and corresponding with a position several centuries earlier than the Asuka era or the tomb's construction (the vernal equinox was shifting into Pisces by the end of the seventh century). Third, since enough stars are seen in *Kitora Kofun* to

determine just which ones could and could not be seen on the horizon, a relatively good estimate of observer latitude can be made. Fourth, the painting of the “White Tiger of the West” is reversed from that of *Takamatsu Zuka Kofun* and tombs with similar paintings found in China. In *Kitora Kofun*, the tiger is painted facing north. This point is especially interesting. When looking at the west wall of *Takamatsu Zuka Kofun* (note the photograph of the White Tiger in the Chinese tomb of similar dating in Krupp's *Echoes of the Ancient Skies* 1983, p. 112), the tiger is seen to face south, and this indeed corresponds with the placement of the figure of this animal among the stars. (Editor's note: see a detailed discussion of *Kitora Kofun* in this encyclopedia.)

These tombs provide us with a view of how Chinese/Korean astronomical thought found its way to Japan and how such thought was incorporated into the social purposes of Japan's rulers. It seems evident that it is not the accuracy of the cosmology reflected in the tombs' paintings but rather the almost wholesale adoption of Chinese perceptions to further strengthen the centrality of imperial rule that was most important, especially in the case of *Kitora Kofun*. Japanese rulers wished to give themselves the same legitimacy that Chinese rulers had; incorporation of symbols

and astronomical methods in order to accomplish this did not necessitate complete awareness of the underlying principles, but rather their mere presence. As mentioned earlier, such was the case with the introduction of Buddhism as well as other aspects of Chinese thinking. One can still see this kind of use of foreign import without substantive understanding in the almost playful use of foreign language in what sometimes appears to be gibberish in slogans and advertising of modern Japan. Use of foreign icons brings esteem, regardless of whether or not they are understood. Again, it must be stated that the central beliefs, ritual ceremonies, and social purposes of Japan appear to have remained and do remain somewhat constant regardless of import, such imports merely being incorporated within this larger “spring.”

Adapting Chinese Lore to Native Beliefs and Purposes: Orihime, Kengyuu, and Tanabata

When we look at the adaptation of myth and legend imported from other cultures, we also find the obvious sense of indigenous Japanese values and socio-political purposes infused over time. Perhaps one of the best examples of this is the legend of Orihime and Kengyuu (Nojiri, 1973). This story and associated festival were probably imported from China in the Heian era (794–1185). The story involves the stars of Vega and Altair, and the reader should consult Krupp (1991) for an explanation of the story in its Chinese form. Essentially the same in character, there are some noticeable adaptations made based on the unique social and pragmatic needs of Japanese culture. In Japan, the star Vega is often called Orihime Boshi (Weaving Princess Star), and Altair is often called Kengyuu Boshi or Hiko Boshi (Puller of Cows Star). To give the reader one Japanese version of the legend, we will paraphrase Hara (1975).

One day, the emperor’s daughter, Orihime, was sitting beside the Milky Way. She had been weaving because her father, the emperor, “wished it” (he loved the beautiful clothes that

she made). On this day, she was very sad because she realized that she had been so busy that she did not have time to fall in love. Her father, Tentei, the ruler of the heavens, felt sorry for her and arranged a marriage with Kengyuu (who lived across the river, the Milky Way). Their marriage was one of sweetness and happiness from the start, and everyday thereafter, they grew happier and happier. But Tentei became very angry, because in spending so much time in her happy marriage, Orihime was neglecting her weaving. Tentei decided to separate the couple, so he placed them back in their original places, separated by the Milky Way. On only one night of the year would he allow them to meet, the 7th day of the 7th month. Every year on that day, from the mouth of the river (the Milky Way), the boatman (of the moon) comes to ferry Orihime over to her beloved Kengyuu. But if Orihime has not done her weaving to the best of her skills and ability, Tentei may make it rain. When it rains, the boatman will not come (because the river is flooded). However, in such a case, *Kasasagi* (a group of magpies) may still fly to the Milky Way to make a bridge for Orihime to cross.

Related to this legend, ancient Japanese celebrated the festival of *Tanabata* on the 7th day of the 7th month each year (lunar calendar). The 7th day of the 7th month generally falls in August or September in the Gregorian calendar. At this time of the year, the constellations of Lyra and Aquila are prominent in the evening sky with their major stars (Vega and Altair) separated by the Milky Way. The 7th day of the 7th month also finds a waxing crescent moon (boat) reaching its first quarter. If it is not raining, both *Orihime Boshi* (Vega) and *Kengyuu* (Altair) are quite conspicuous at the time of the *Tanabata* festival.

Tanabata may be translated as “weaving with the loom (*bata*) placed on the shelf (*tana*),” and the festival celebrates improvement of technical skill and ability. As in China, ancient Japanese added specific values to their wishes that Orihime should hone her skills and work hard so that she could meet Kengyuu. In modern celebrations of *Tanabata*, people throughout Japan write wishes (generally for themselves or relatives) to the *kami* Orihime on colorful strips of paper. On the

evening of Tanabata, they tie these paper wishes to freshly cut bamboo. Wishes may be for increased skills in work or school but may also be for anything that reflects a person's dreams and hopes for the future. Summer vegetables such as eggplant and cucumbers are prepared, and horse or cow figures made out of straw and water oats are decorated.

While the myth probably held seasonal significance in its Chinese origins, specifically the celebration of the end of the rainy season (reflected in a desire that it not rain), it found a variety of interpretations related to seasonality in its Japanese form. Particularly in relation to agricultural development in Japan, "wishes" related to celebrations of *Tanabata* ranged from desire for dry weather to desire for wet weather depending on the particular geographic region and whether a crop was to be planted or harvested at this time.

Following Shinto practice and ancient values, the concept of purification (generally including use of water) before the Bon Festival (centered on the 15th day of the 7th month) was also added to the *Tanabata* festival. Before the legend was brought from China, a ritualistic festival had been held to welcome the water kami at this time of the year; infusion of the legend of Orihime and Kengyu added a motif of the ritual celebration of the marriage of a weaving lady and the water god (Okada & Akune, 1993). In eastern parts of Japan, an associated ritual called Nebuta was celebrated. On the early morning of Tanabata, bamboo would be set afloat in the river, and people would brush their bodies with leaves from "silk" trees. By doing so, they were said to take their sleepiness (*nebuta*) away, another form of purification and preparation for Bon (Yoshinari, 1996). The close relation of Tanabata to the indigenous Bon Festival has obviously led to a number of adaptations of the imported Chinese mythology. In short, one makes the coming of the Bon Festival sacred by excluding impure spirits from the body at the first quarter moon, thus being pure for the coming of Bon at full moon. It is interesting that in some regions of Japan, *Tanabata* is accompanied by a taboo forbidding swimming or bathing in a river. Noting the relation with the celestial

Astronomy in Japan: A Cultural History,

Fig. 3 Decorated strip of *Tanabata* bamboo from the Tottori region of Japan.

Note the representation of *Hiko Boshi* (Altair and two-flanked stars in Aquila) at the top and *Orihime Boshi* (Vega flanked by two stars in Lyra) near the middle (From Nojiri, Houei Nihon Seimei Jiten of Star Names in Japan, 1973, p. 60. Used with kind permission of the publisher)

"river" or Milky Way, the taboo is based on the idea that a *Kappa* or water deity resides in the river and one should not make the pure water dirty by entering the water deity's home.

When it was first imported, *Tanabata* was celebrated only by imperial court officials. It was considered a graceful event, full of the simple elegance so associated with the Heian era of Japan. Lanterns were lighted, and poems were written on mulberry leaves still holding their dew (Nojiri, 1973). Of course, as the custom spread to local areas, towns became covered with bamboo at *Tanabata*, and the festival took on more of the values inherent in Japanese consciousness and purpose (Fig. 3).

The process of adapting this imported legend and developing indigenous practices evolved in complex ways over the centuries, and we have touched on but a bit of this complexity. In modern times, the festival is generally celebrated on a solar July 7th, a date that is generally still within the rainy season. Sadly, the festival has lost much of its seasonal significance with modern industrialization. Of course, the vitalistic ethic of improved work and skill is still valued, regardless of whether or not the day of celebration is attuned astronomically.

Prevalence of the Sun: Akemashite Omedetou Gozaimasu

No discussion of Japan's heritage with the sky can avoid the prime significance of the sun. Symbolism related to the sun is heavily incorporated in Japanese myth and is still seen in its flag. Being the most eastern of East Asian nations and indeed being seen as the land which the sun first greets in the morning, the phrase "Land of the Rising Sun" developed special meaning for Japanese from ancient times. Along with the significance of Amaterasu as sun goddess, there are other ways in which the sun has become a central part of Japanese consciousness. The celebration of the New Year represents yet another way in which indigenous values are mixed with Chinese imports to provide a unique cultural perspective on the significance of vitalism and optimism.

While Christmas is celebrated in Japan to some degree, it is not considered a national holiday, and the attendant Western religious aspects of that day are certainly missing. New Year's Day is by far the more significant holiday. Before the Meiji Restoration, the New Year was celebrated according to the Chinese lunar calendar. In modern times, though the lunar calendar still has influence on scheduling of festivals and celebrations, the Gregorian calendar change is celebrated by most people as the "official" New Year.

In the days before the New Year begins, people busily prepare by cleaning the house and cooking food to welcome the kami of new life. At this time, the post office is flooded by New Year's cards which each person sends to friends, relatives, and associates. Rail and air terminals are jammed with people trying to get back to their hometowns to spend the New Year's "night" and "daybreak" with family members.

Japanese express wishes for the New Year by saying "Akemashite Omedetou Gozaimasu." Only one kanji (Chinese character) is found in this phrase (within the first word). This kanji is a combination of the characters for sun and moon and, among other meanings, entails the sun and the moon getting together and becoming "bright." It represents "changing" and "opening," in a sense, "dawning" (Fig. 4).

明

Astronomy in Japan: A Cultural History, Fig. 4 The *kanji* for *Ake*. Symbols for the sun and moon are placed together in this character to represent "bright" or "beginning" (Computer graphic by Steven L. Renshaw)

In ancient lore (under the lunar calendar), the New Year was seen in relation to change in both the sun and moon as well as the symbol of their luminance. The meaning of the phrase "Akemashite Omedetou Gozaimasu" reflects the values of linealism, vitalism, and optimism. Perhaps it is expressed in English most appropriately as follows: "The year is changing; darkness gives way to light; new life begins; Congratulations!" Following tradition, many Japanese on New Year's morning brave the cold to find places with unobstructed views of the eastern horizon and eagerly await the rising sun, the break of day, the symbol of new life. Incorporating the ideas of much ancient mythology, the sun is seen to be making its journey back to the north, and the vernal equinox is eagerly awaited.

As in other aspects of Japanese astronomy that we have discussed, Chinese imports and traditions were incorporated from early times. The New Year of 2008 was special in that it began another 12-year cycle of the Chinese calendar (based on positions of Jupiter with its 12-year orbit and consequent position about the ecliptic; Uchida, 1981). The tradition of using Chinese-based animal names for the 12 directions and associated years is popularly maintained in Japan. In 2008, things turned around once more to the direction of *ne* (mouse), the north, to the direction of the star Polaris, sometimes called *Ne no Hoshi* (mouse star) but also called *Shin Boshi*, the "Heart" star, the "soul of the Heavens." 2008 began the clockwise cycle again which from ancient Chinese geomancy means moving from N to NNE (2009, *ushi* or cow), to ENE (2010, *tora* or tiger), to E (2011, *u* or rabbit), and so forth.

The mixture of Chinese geomancy and symbolism with indigenous social values is clearly seen in the Japanese celebration of the New Year. Yet the quiet tolling of temple bells on New

Year's Eve brings a certain calm and solitude unseen in most any other culture. It is in this very symbolic act that centuries of Japanese history and tradition, for better or worse, can be seen and truly appreciated.

Hopes for the Future Built on a Rich But Hidden Past

Most of Japan's recorded history reflects a culture continually influenced by imports, even when on the surface, the country appeared to be isolated. At the same time, a cultural consciousness combined with quite distinct social and political purposes has always been a source through which most any idea, foreign or domestic, had to be filtered.

Though we can still see much of the ancient heritage of Japanese astronomy in layouts, structures, mythology, and ethnographic lore, it is often difficult to find too many Japanese citizens aware of this sphere which incorporates a complex interaction of ancient values and purposes with celestial symbols. Feeling that the culture has adopted almost every modern concept that East or West has to offer, many Japanese themselves are unaware of the richness of their ethnoastronomic heritage. As in the West, many young Japanese are more likely to know the name of Pleiades rather than Subaru and associate the latter with an automobile company rather than the celestial symbol which meant so much to their ancestors. While Tanabata is still observed and the legend of Orihime and Kengyuu still finds its way into modern songs and prose, few people are concerned about the festival's shift away from its seasonal association. In many ways, however, Japan's embracing of the West and virtual denigration of its past reflects a process which has been a part of the culture's way of handling infusion from its earliest times. Still, when the "face" is lifted, one still finds an enduring set of values and purposes that appear to predate written history.

In discussing some modern approaches to archaeoastronomy, Aveni (1989) has alluded to the inclination to disassociate science from the social and historical context in which it was

developed. He points out how such isolation lacks the notion of process or change and in a sense leads to a "predetermined goal of seeking ourselves out in the tattered pages and crumbling walls of other peoples' history (p. 8)." Aveni further mentions the danger of relying solely on written records and emphasizes using additional evidence in the form of archaeology and architectural icons to understand a nation's cultural astronomy. In taking a narrow view of astronomy as it developed into modern Western science, Aveni contends that we pursue what is interesting to us instead of what was important to the people we study.

The specific irony of Aveni's observations relative to the study of astronomy in Japan may rest in the view taken by many Japanese themselves. In a sense, the view is that we (Japanese) seek others' selves (Western science in particular) within the tattered walls of our own culture and come up sadly lacking. To further paraphrase, we (Japanese) tend to pursue what is of modern interest (to the West in particular) instead of what was actually important to our own ancestors throughout history. These perhaps enigmatic Japanese views are the result of a long and complex history involving interaction of native belief and consciousness with a perception that while unique, the native culture is somehow inferior to those imports it filters. Such lack of "cultural self-esteem" has led to a number of enigmatic events in Japanese history, not merely the denigration of its own astronomical heritage.

In looking at the overall influence of Japanese value, past and present, it may be worth noting that modern astronomical practice, while totally within the rubric of Western science, reflects a long heritage of curiosity combined with concern for future generations. A good example of this may be found in the diary of a young Kochi resident rediscovered in the 1980s. In 1664, while astronomers in Europe were trying to learn more about the motion and nature of comets, Matasaburou, a young boy age 12, began to observe what would later be known as Comet C/1664 W1. Encouraged by his teacher, Jian, he diligently observed the comet for over 4 months, wrote his impressions, and drew the changing

shape of the comet in his diary. Despite the lack of astronomical knowledge, Matasaburou showed remarkable curiosity about the true nature of the *houki boshi* (brush star) and an abundant skepticism of the prevailing view among townspeople that the comet signaled doom. While his drawings do not have the flamboyance of those of Hevelius and others observing the comet in Europe, his diary shows every attempt to precisely plot the location and shape of the comet as it crossed the celestial sphere nightly. Matasaburou passed on to his own pupils the joy of discovery, and it is no doubt due to this that copies of his diary have survived the centuries. Such diligence is still seen in the work of amateur and professional astronomer alike. One cannot help but be reminded of the tireless efforts of professionals and amateurs who venture out on every clear night to observe and try to discover yet another celestial wonder.

Future astronomers, archaeoastronomers, and ethnoastronomers in Japan will no doubt come from an increasing number of young Japanese who have grown up in the intellectually free environment of modern Japan. Those not raised within the culture may find the door to Japan's astronomical past opening wider if there is a will to engage in exploration of consciousness and purpose still so evident beneath the surface of Japan's modern society. However, much work lies ahead in uncovering the vast richness of Japanese astronomy in history, and the future is probably most "optimistic" for those young Japanese scholars who find the riches of their heritage and culture inspiration and justification enough to seek knowledge about their nation's long pilgrimage with the sky.

Astronomy in Mainland Southeast Asia

Yukio Ōhashi

Southeast Asia is divided into two parts, mainland Southeast Asia and insular Southeast Asia (also called the Indo-Malay Archipelago). Mainland Southeast Asia is further divided into two parts. One is Vietnam, where Chinese influence is

greater than Indian influence, and the other includes Burma, Cambodia, Laos, and Thailand, where Indian influence is greater. The Malay Peninsula is a part of mainland Southeast Asia geographically, but is culturally closer to insular Southeast Asia.

Astronomy in Burma, Cambodia, Laos, Thailand, and Yunnan

Traditional Calendars in Burma, Cambodia, Laos, Thailand, and Yunnan

The traditional calendars of Burma, Cambodia, Laos, and Thailand in Southeast Asia, and those of the Tai (or Dai in the Pinyin system of Chinese transliteration) people in Sipsong-panna (or Xishuang-banna in Pinyin) in the Yunnan province of China have similar characteristics. (For the calendars in mainland Southeast Asia, except for Vietnam, see Eade (1989, 1995). For the Burmese calendar, see Irwin (1909), de Silva (1914), and Htoon-Chan (1918). For the Cambodian calendar, see Faraut (1910). For the Lao calendar, see Phetsarath (1940) and Dupertuis (1981). And also, for the Dai calendar in Yunnan in China, Zhang and Chen (1981) may be consulted. It may also be mentioned here that de Casparis (1978) may be consulted for calendars in insular Southeast Asia.) They are basically based on the Indian (Hindu) calendrical system, which is a luni-solar calendar, with certain simplifications. The Indian influence is seen, for example, in the fact that the length of a year used in most of these calendars is 365.25875 days. This is similar to the sidereal year (not tropical year) of the Ārdharātrika school, one of the schools of Hindu astronomy. Dikshit, an authority on Hindu astronomy in the second half of the nineteenth century, pointed out that the length of a year used in an astronomical work procured by a French envoy from the Ayutthaya dynasty of Siam (present Thailand) is the same as that of the *Sūrya-siddhānta* quoted in the *Pañca-siddhāntikā* of ► [Varāhamihira](#) (sixth century AD) (Dikshit, 1981, p. 378). This *Sūrya-siddhānta* belongs to the Ārdharātrika school.

Besides the Indian influence, there is also Chinese influence in this area, notably the animal names of the 12-year cycle.

The main differences between Indian (Hindu) traditional astronomy and the calendars in mainland Southeast Asia (except for Vietnam) are as follows. (The traditional calendar of Vietnam is based on the Chinese system, which I shall discuss in the next section.)

1. In the Hindu traditional calendar, an intercalary month is inserted when two successive new moons occur during which the sun remains in the same zodiacal sign. In mainland Southeast Asian calendars, the 19-year cycle is usually used for intercalation during which seven intercalary months, which consist of 30 days, are inserted after the fixed month of a year. Actually, the 19-year cycle is not harmonious with the sidereal year which is used in Hindu and mainland Southeast Asian calendars, and I suspect that this 19-year cycle might have been introduced from China.
2. In the Hindu traditional calendar, 1 month is divided into 30 *tithis*, which are the periods during which the longitudinal difference between the sun and moon changes by 12° , and the number of the *tithi* at the beginning of a day (usually sunrise) becomes the name of the day. So, the number of days in a month is automatically determined. In mainland Southeast Asian calendars, 29-day months and 30-day months are usually distributed alternately at definite months of a year, and 11 intercalary days are distributed in 57 years at the fixed month of a year. Actually this method is slightly inexact.

One thing may be added here. Among Tai (or Thai) people, lunar months are named by serial number, and there are some variations of this method. This method is similar to the Chinese method, but is absent in the Hindu traditional calendar. The method used by Dai people in Sipsong-panna in Yunnan province (in China) is quite similar to an ancient variation of a Chinese method.

I suggest the following tentative hypothesis. The 19-year cycle intercalation and the method of month reckoning using serial numbers were introduced from China, and were modified after the introduction of the Indian calendar (Ārdharātrika school). (For details, see Ōhashi, 2002). It may also be mentioned here that the calendar used in the inscriptions of Champa, which was a kingdom that existed in present central and south Vietnam until the seventeenth century AD, was also based on the Indian calendar.

Controversy Regarding the Dai Calendar in Yunnan, China

There was a controversy between Dong Yantang and Zhang Yong, both of whom are Chinese scholars, in the first half of the twentieth century regarding the origin of the Dai peoples' calendar in the Yunnan province of China. In 1938, Dong Yantang published a paper on the origin of the Dai calendar (Dong, 1938). In this paper, Dong Yantang argued that the Dai calendar was based on the Qin calendar of ancient China.

In 1939, Zhang Yong wrote a paper on the Dai calendar (Zhang, 1939). Zhang Yong criticized Dong Yantang's paper, and concluded that the Dai calendar was based on the Indian calendar. Zhang Yong pointed out some reasons. For example, the Dai calendar uses half months just like the Indian calendar, and the Dai calendar divides a year into three seasons just like the Indian calendar. These reasons are justified. Zhang Yong mentioned other reasons also, and tried to show that the Dai calendar was completely based on Indian calendar without Chinese influence.

I think that the Dai calendar is basically based on Indian calendars, but there may be some Chinese influence also, as I mentioned in the previous section.

Historical Development of the Traditional Calendars in Yunnan and Burma

According to Zhang Gongjin and Chen Jiujiu (Zhang and Chen 1981), the texts entitled *Suding* and *Suliya* were followed by the Dai people for making calendars before AD 1931, but the text

entitled *Xitan* has been followed since AD 1931 or so. Zhang and Chen also say that the *Suding* and *Suliya* do not follow the 19-year cycle of intercalation strictly, but the *Xitan* follows the 19-year cycle of intercalation. The calendrical luni-solar year of the *Xitan* practically keeps pace with the tropical year, although the solar new year's day is calculated by the sidereal year as before. I compared their astronomical constants with Indian constants, and found that the *Suding* and *Suliya* follow the Ārdharātrika school, while the *Xitan* follows the Saura school (Ōhashi, 2002).

According to Irwin (1909), the *Makaranta* (there are two methods of epoch: AD 638 and AD 1436), which probably follows the "original *Surya Siddhanta*" (i.e., Ārdharātrika school), was followed in Burma originally. Afterwards the *Thandeikta* (epoch: AD 1738), which chiefly follows the "present *Surya Siddhanta*" (i.e., Saura school), was used. Irwin writes that the *Thandeikta* is said to have been composed in about AD 1738 or AD 1838, and that the present *Sūryasiddhānta* was introduced into Amarapura, Burma, in AD 1786, and translated into Burmese after about 50 years. Irwin also states that the 19-year cycle of intercalation was followed in the *Makaranta*, but was not strictly followed in the *Thandeikta*. We should note that the Burmese *Makaranta* is probably different from the well-known Indian Sanskrit astronomical table *Makarandasāraṇī* (AD 1478) of ► [Makaranda](#), which follows the Saura school.

Here, the treatment of the 19-year cycle of intercalation is just the opposite of the Dai calendar (Yunnan, China) and Burmese calendar. More detail about the calendar reform in these regions should be investigated.

Traditional Astronomy and Modern Astronomy in Thailand

In the mid-fourteenth century AD, Lithai (King Ruang) of the Sukhothai dynasty wrote the *Traiphum* (Three Worlds) (Reynolds & Reynolds, 1982). This is a celebrated text of traditional Thai cosmology, which is based on Buddhist cosmology. Some information about traditional astronomy and the calendar is also found there.

In 1685, King Narai of the Ayutthaya dynasty observed a lunar eclipse with a telescope with the Jesuits sent by the French King (See Tachard, 1688/1981, pp. 230–246; Choisy, 1993, p. 215). King Narai requested mathematicians from France, and planned to build observatories at Louvo (now Lop Buri) and Siam (now Ayutthaya). This event may be considered the beginning of modern astronomy in Thailand.

In 1687, a French envoy, Simon de la Loubère, visited the Ayutthaya dynasty and procured an astronomical work entitled *Souriat*. This work was later analysed by a celebrated astronomer, Jean Dominique Cassini (See Loubère, 1693/1969, pp. 64–67 and 186–199; Bailly, 1787). This is the earliest information of India-based astronomy reaching Europe. Dikshit pointed out that the length of a year used there is the same as that of the *Sūryasiddhānta* quoted in the *Pañcasiddhāntikā* of ► *Varāhamihira* (sixth century AD) (Dikshit, 1981, p. 378).

In the nineteenth century, King Mongkut (Rama IV) (r. 1851–1868) studied European astronomy as well as Thai traditional astronomy. He ordered his own observatory near Phetburi. He predicted the total solar eclipse of 1868. According to the *Dynastic Chronicle*, the King calculated the eclipse “by using the old astrological texts of Siamese and Mon, as well as many old American and English texts.” According to Thongchai, the Mon text used by the King is the *Saram*, one of the two Mon treatises for planetary calculation known in Siam; the other text more conventionally used by astrologers at that time was *Suriyayat*. (See Thiphaakorawong, vol. 2 1966 of 1965–1974, pp. 532–539; Cook, 1992; Thongchai, 1994, chapter 2). This was a symbolic event in the course of the introduction of modern astronomy into Thailand.

There are several inscriptions with calendrical data in Thailand, which are also important sources of Thai astronomy (Eade, 1996). There was an independent kingdom, Lanna, in North Thailand from the end of the thirteenth century to the beginning of the twentieth century. The people of Lanna had their own astronomy, which was based on Indian astronomy. (See Soonthornthum, 1998; for the Northern Thai calendar, see Davis, 1976).

Burmese Constellations

Burma has a special system of constellations, and there are three beautiful star maps drawn on the ceilings of corridors of the Kyauktawgyi Pagoda at Amarapura (near Mandalay, Burma) (Fig. 1a–d are the star maps photographed by the author in 1984).

King Pagan (r. 1846–1852) built the Kyauktawgyi Pagoda in 1847 on the model of the Ananda Temple at Pagan (Lu Pe Win, 1960, p. 5). There is a pioneer study of Burmese constellations by Francis Buchanan (1799) (also see Nishiyama, 1997). Although Burmese constellations include Indian constellations, there are many Burmese unique constellations, which are very important for investigating the original Burmese contribution.

Astronomy in Vietnam

There are four main countries where Classical Chinese was used as the official language of traditional learning: China, Korea, Japan, and Vietnam. In this section, I will discuss some aspects of Vietnamese astronomy based on the sources I consulted. When a Vietnamese or East Asian person is referred to in this section, the surname is written first as is the custom in these regions, unless commented upon otherwise.

Previous Researches

In 1934, Mikami Yoshio, a pioneer of the study of the history of Eastern ► *mathematics in Japan*, wrote a paper on a mathematical work of Vietnam. This is a study of a Vietnamese mathematical work entitled *Chi-minh toan-phap*, written in classical Chinese, which was brought to Japan by Matsumoto Nobuhiro, an authority on Vietnamese study in Japan.

In 1940, Yung Chang (as transliterated in his own paper where Chang is the surname, or Zhang Yong in modern Pinyin transliteration) (1911–1939), a Chinese scholar, wrote a paper on the Vietnamese calendar. This is a pioneer study of the Vietnamese calendar, and I was much impressed by this work. In the 1960s,

Astronomy in Mainland Southeast Asia, Fig. 1 (continued)

Astronomy in Mainland Southeast Asia, Fig. 1 Star maps drawn on the ceilings of corridors of the Kyauktawgyi Pagoda at Amarapura

Huard and Durand wrote popular articles on the history of Vietnamese science (Huard & Durand, 1961/1965; Durand & Huard, 1964/1966). In 1964, Ho Peng-Yoke wrote a paper on the records of natural phenomena, including astronomical phenomena, recorded in a historical work of Vietnam. It is necessary to continue this kind of work, comparing the records with other East Asian records, and checking them with modern calculations.

In 1979, a monograph on the history of science in Vietnam was published in Vietnamese in Hanoi (Vien Su hoc, 1979). This book includes 12 papers, including a paper on the history of Vietnamese mathematics written by Ta Ngoc Lien. As far as I know, this book is the most detailed work on the history of science and technology in Vietnam. In 1991, Han Qi, a Chinese scholar, wrote an overview of the history of astronomy and mathematics in Vietnam (Han, 1991). [Ed. note: See Han Qi's article on Jesuits and Knowledge Exchange in China in this volume].

In 1999, the ninth International Conference on the History of Science in East Asia was held at Singapore. In this conference, there was a session on "New Topics in the History of Science in East

Asia-Preliminary Research on Vietnamese Scientific Tradition." In this session, Chu Tuyet Lan and Nguyen Xuan Dien from the Institute of Sino-Nom Studies, Hanoi, introduced Vietnamese works on science, medicine and technology (Nguyen, 2002), and Alexei Volkov read a paper on the *Toan-phap dai-thanh* of Luong The Vinh, a Vietnamese mathematical work. I think that this conference marked a kind of breakthrough for the study of the history of Vietnamese astronomy and mathematics.

In 2000, I visited the Institute of Sino-Nom Studies in Hanoi, and consulted some Vietnamese astronomical works with the help of Ms. Chu Tuyet Lan and Mr. Nguyen Xuan Dien. When I visited Vietnam, I found a small book on 13 Vietnamese scientists, both premodern and modern, written in Vietnamese (Le, 1999). This is a popular book for youths.

In 2002, Alexei Volkov published a paper on the *Toan-phap dai-thanh*. I think that this is a monumental paper on the history of mathematics in Vietnam. Also in 2002, a convenient bibliography of classical literature of Vietnam was published in Taiwan. Several astronomical and mathematical works are listed there (Liu, Wang & Chen, 2002, part 1, pp. 452–459).

Vietnamese Astronomy

Rough History of Vietnamese Calendars

1. Acceptance of Chinese calendars, notably the *Shoushi* calendar

The *Yuanshi*, the official history of the Yuan dynasty of China, says that a Chinese calendar was given to the Vietnamese king (Tran dynasty) in 1265 (*Yuanshi*, vol. 209, Annan, the second year of Zhiyuan). At that time, the *Shoushi* calendar, the celebrated calendar of the Yuan dynasty, had not been made, and the *Daming* calendar of the previous Jin dynasty was still used in China.

The *Dai-Viet su-ky toan-thu*, an official history of Vietnam written in Classical Chinese, says that the *Shoushi* calendar was given to a Vietnamese king (Tran dynasty) from the Chinese Emperor in 1324. (*Dai Viet Su Ky Toan Thu*: 220, vol. 6, 42 b in the original block print). From the above sources, we can suppose that Chinese calendars were accepted in Vietnam until the early fourteenth century.

2. *Hiep-ky* calendar

The *Dai-Viet su-ky toan-thu* states that the *Shoushi* calendar was changed into the *Hiep-ky* calendar in 1339 (Tran dynasty) (*Dai-Viet su-ky toan-thu*: 229, vol. 7, 9 b-10 a in the original block print). This record possibly means that the name of the calendar was changed, and does not necessarily mean that the method of calculation was changed. The *Mingshi*, the official history of the Ming dynasty of China, says that the *Datong* calendar of China was given to the Vietnamese king (Tran dynasty) in 1369, the next year of the establishment of the Ming dynasty (*Mingshi*, vol. 321, Annan, the second year of Hongwu). It may be that the *Datong* calendar, which is a revised version of the *Shoushi* calendar, was accepted in Vietnam at that time.

3. *Thuan-thien* calendar

The *Dai-Viet su-ky toan-thu* tells that the *Hiep-ky* calendar was abolished, and the *Thuan-thien* calendar was adopted in 1401 (Ho dynasty) (*Dai-Viet su-ky toan-thu*: 267, (vol. 8, 39a in the original block print).

The difference between these two calendars is not recorded.

4. Acceptance of the Chinese *Datong* calendar

Vietnam was directly ruled by the Ming dynasty of China from 1413 to 1428, and the *Datong* calendar must have been used. The Le dynasty was founded in 1428 in Vietnam, but there is no record that the calendar was changed.

The *Mingshi* states that the *Datong* calendar was given to the Mac, who ruled Vietnam for certain period, in 1540 (*Mingshi*, vol. 321, Annan, the 19th year of Jiajing). In 1829, Nguyen Huu-than wrote in his *Y-trai toan-phap nhat-dac-luc* that the *Datong* calendar had been used until the *Hiep-ky* calendar (Vietnamese adoption of the Chinese *Shixian* calendar) was adopted in 1813 (Zhang, 1940, p. 34.).

5. *Hiep-ky* calendar (= *Shixian* calendar)

According to Nguyen Huu-than, as we have seen above, the *Shixian* calendar of the Qing dynasty of China was adopted in Vietnam as the *Hiep-ky* calendar in 1813 (Nguyen dynasty). This *Hiep-ky* calendar should not be confused with its previous namesake. Zhang Yong compared Vietnamese chronological tables with Chinese calendar, and pointed out that the *Shixian* calendar was actually used in Vietnam from 1813 to 1840.

6. Consideration of the longitudinal difference

Zhang Yong pointed out that the Vietnamese *Hiep-ky* calendar has differed from the Chinese *Shixian* calendar since 1841. This must be due to the consideration of the longitudinal difference between Vietnam and China.

Calendar Reformation Under Minh-manh

In order to reform the calendar, astronomical observations were made under the emperor Minh-manh (r. 1820–1840) of the Nguyen dynasty. There are some source materials about this reformation.

The *Dai-Nam hoi-dien su-le* (1855) is a comprehensive official record of the system of government of the Nguyen dynasty. It has a section on the Kham-thien-giam (National Astronomical Observatory). According to this section, it was

declared in 1837 that the prime meridian for Vietnam passed through its capital (Hue), whose latitude was determined to be $16^{\circ}22'30''$, and longitude measured from the Western prime meridian to be 105° (*Dai-Nam hoi-dien su-le*, vol. 259, 13a–b). The actual position of Hue is $16^{\circ}27'N$, and $107^{\circ}33'E$ (from Greenwich). So, the above-mentioned Western prime meridian must be Paris ($2^{\circ}20'E$ from Greenwich).

There is another interesting work entitled *Thien-van-khao* (Study of Astronomy), which is volume 1 of the *Su-hoc bi-khao* of Dang Van-phu. This text records longitude and latitude (from Hue) of several places determined in 1837. According to this text, the longitude seems to have been determined by the observation of lunar eclipses using local time. From the above sources, we know that Vietnamese astronomers made efforts to make the calendar more suitable for Vietnam.

Another interesting work is the *Quoc-trieu thien-van-chi*. This is a chronological compilation of the records of heavenly phenomena from 1569 to 1888.

The traditional astronomies in several regions of mainland Southeast Asia are very interesting, but their detailed study is our future task. Several original sources are still in manuscript form or extremely rare. Fortunately, some people are now going to study this subject, and I hope that more results can be reported in the near future.

In the case of Vietnamese astronomy, it is necessary to compare it with Chinese astronomy, and in the case of Burmese, Cambodian, Lao, and Thai astronomies, it is necessary to compare them with Indian astronomy. Thorough study of the regional differences and their relationships with regional cultures are needed. I hope some readers of this article contribute to this subject in the future.

Astronomy in Medieval India

S. M. Razaullah Ansari

Aligarh Muslim University, Aligarh, UP, India

Introduction to Islamic Astronomy

Muslims are obliged to discharge three major religious duties (*arkān*), which could be planned quite accurately using mathematical sciences, particularly astronomy (King, 1993). They are (1) Islamic prayer times that are defined according to the rules of astronomical time reckoning (*ʿIlm al-Mīqāt*), (2) calculating the direction of *Kaʿba* (*Qibla*) – the rectangular-shaped room at the center of the Grand Mosque in Mecca – to which Muslims face while praying, and (3) the sighting of the lunar crescent (*Hilāl*) at sunset, by which begins the first day of every month of the Islamic calendar. Evidently this sighting depends on the position of the Sun and Moon and also their positions with respect to the local horizon. Consequently, in the first few centuries of the spread of Islam (eighth to ninth century), Muslims began an intensive and extensive reception of the natural and even social sciences. A multitude of scientific works from Babylon, India, Iran, and Greece were translated into Arabic. This transmission had an official sanction as well. Beginning with the reigns of Umayyad Caliph ʿAbd al-Malik ibn Marwān (ca. 700) and his successor son Hishām (724–743) and particularly during the reigns of the Abbasid Caliphs al-Manṣūr (754–775), Hārūn al-Rashīd (786–809), and al-Māʾmūn (813–833), the transmission of foreign or ancient sciences achieved its climax. At this time, Sasanian, Indian, and finally Greek astronomy and mathematics were assimilated and led to the writings of great scholars. Some of these are al-Khwārizmī, al-Farghānī, and al-Battānī (ninth to tenth centuries); Ibn Sīnā, Ibn al-Haytham, and al-Bīrūnī (eleventh century); and Naṣīrūddīn al-Ṭūsī (thirteenth century), to name just the most important ones. For example, al-Ṭūsī was the director of the Marāgha observatory, and he initiated the

so-called *Hayʿa* tradition by developing a non-Ptolemaic theoretical model of planetary motion. For details see Saliba (1994).

India was ruled by the sultans of Central Asia and their descendants during the Sultanate period (1191–1526). The Indian Mughal period (1526–1857) began with the dynastic rule of Ṣāḥīrūddīn Bābur (reigned 1526–1530), followed by his son Humāyūn (r. 1530–1556) and Akbar (r. 1556–1605) whose grandson Shāhjahān (r. 1627–1658) is famous for building the Tāj Maḥal at Agra. During the Indian medieval period, both sultans and particularly Mughal emperors were very keen to patronize the scholars from Central and West Asia. Those scholars (*Ulamā*, *Fuḍalā*), including also mathematicians and astronomers, thronged the courts of sultans, emperors, and even local rulers and nobles (*Umarā*). They brought with them various scientific (mathematical and astronomical) texts, such as the writings of Abuʿl Rayḥān al-Bīrūnī (d. 1048), Naṣīrūddīn Ṭūsī (d. 1274) of Marāgha, Sulṭān Ulugh Bég (d. 1449) of Samarqand, and Bahāuddīn al-ʿĀmilī (d. 1622). Mughal Emperor Bābur (prior to his conquest of India) had forged an alliance with the Shāh Ismāʿīl-I of Persia and his son Emperor Humāyūn, who had bonded a friendship with Shāh Tahmāsp bin Ismāʿīl (d. 1576). Consequently, even during the following reigns of Mughal emperors, Akbar, Jahāngīr, and Shāhjahān, the cordial relationship with Iranian Safavid rulers, namely, Shāh ʿAbbās-I (d. 1629) and Shāh ʿAbbās-II (d. 1666), strengthened further (Riazul Islam, 1970). An interesting anecdote is that Shāh ʿAbbās-I sent to Jahāngīr on his request as gift the *original* astrolabe of Sultan Ulugh Bég – the founder of the astronomical observatory at Samarqand in 1420. The Shah of Iran kept for himself only its copy (Riazul Islam, 1970). Evidently in such a politico-cultural milieu, several Iranian/Central Asian scholars and scientists flocked to the courts of medieval Indian sultans and emperors who patronized them liberally. In this context, one may understand the origin of the exact sciences, e.g., astronomy and mathematics, which were transmitted to the Indian subcontinent during the medieval period and which were developed further by indigenous

Indian scholars (for a survey on Islamic astronomy and its transmission into India, see Ansari (1995), Appendix I).

A specific feature of Islamic astronomy was the emphasis on observational astronomy. Even in the early Abbasid period (750–850), astronomical observatories were established, in which practical astronomy was carried out quite diligently. The earliest observatories, the Shammāsiya and Qāsiyūn observatories, both founded by Caliph al-Mā'mūn (d. 833), resulted in an observatory movement which culminated in the establishment of the Marāgha observatory in 1259 (Director, Naṣīruddīn al-Ṭūsī), the Samarqand observatory in 1420 (founded by Sulṭān Ulugh Bég, for whom see van Dalen (2007b)), and the Istanbul observatory in 1575–1577 (Director, Taqī al-Dīn Muḥammad) (see for details Sayili (1960) Chapters II, VI, and VIII). An important task at those observatories (*Raṣad Gāh/Khāne*) was the compilation of *Zīj* (plural *Zījāt*), which are astronomical-mathematical tables or handbooks to be used for determining the position of the Sun, Moon, and various planets. All *Zīj*es, in Arabic, Persian, Hebrew, and Turkish, contain tables for functions of spherical astronomy and of trigonometrical functions. The compilers deal briefly also with the following topics: solar and lunar parallax and their eclipses, lunar visibility, gazetteers, star catalogues, and tables of ascendants for astrological purpose. To overview the *Zīj* literature, cf. the pioneering survey by Kennedy (1956), an updated interim report by King and Samso (2001), and the comprehensive *Zīj* survey of about more than 200 *Zīj*es by van Dalen (2007a). For *Zīj*es compiled in India, see also Ansari (2014), forthcoming.

Zijes of the Sultanate Period

Zij-i Nāṣirī (ZN)

We know now that this was the first Indian *Zīj* of the period written by Maḥmūd ibn 'Umar al-Rāzī, who dedicated it to Naṣīruddīn Maḥmūd bin Sulṭan Shamsuddīn Iltutmish (r. 1246–1265 in Delhi), hence its title, abbreviated hereafter as

ZN. Storey (1972, pp. 74–75) informed about only one manuscript then extant in the Ḥusayn Agha Nakhjawānī Library (Tabriz), which does not seem to exist now. For its brief history, cf. Ansari (2008, pp. 62–63). Fortunately I have been able to find another complete manuscript of this *Zīj*, in the Āyat Allāh Najafī Mar'ashī Library (Qum), Ms. 9176, comprising 165 ff., copied close to the time of the author (see Ḥusaynī & Mar'ashī, 1994, p. 293). Note that Emperor Akbar's chronicler Abū'l Faḍl 'Allāmī mentioned ZN in the list of 86 *Zīj*es given in his book: *Ā'in-i Akbarī (Institutes of Akbar)*. It means that it was available in India even in the sixteenth century. In the first *rukn* ("pillar") on fol.111a, 65 fixed stars (*Thawābit*) are catalogued for the year 615 Yazdigird (AD 1246) with their longitudes and latitudes. In one of his numerical examples (fol.10b), the given date is Thursday 22 Sha'bān AH 641 (4 Feb. AD 1244). The author's base meridian is Delhi. In fact, his numerical examples lie mostly between AD 1235 and 1245, during which time Maḥmūd ibn 'Umar evidently had been compiling his *Zīj*. In other words this first Indian *Zīj* was compiled even before *Zīj-i Ilkhānī* (AD 1271) of Naṣīruddīn Ṭūsī at Marāgha observatory.

ZN consists actually of two *rukn*, the first of which contains tabulated material for detailed calculations of heavenly bodies in 66 chapters (120 ff). The second *rukn* (paginated afresh) deals with the theory or general principles of astronomy, illustrated by direct calculation without recourse to tables; it consists of 60 chapters (44 folios). The topics are chronology; functions of trigonometry and spherical astronomy; planetary positions, conjunctions, and eclipses; astrology; and geographical tables. According to a detailed comparative study by Dalen (2004, p. 831), the mean motions in ZN were calculated with very high accuracy, and these tables agree with *Zīj al-'Alā'ī* compiled in Arabic by al-Fahhād, who is mentioned by Maḥmūd ibn 'Umar in his list of 14 astronomers, whose *Zīj*es he studied particularly (fol. 1b-2a of ZN). 'Abd al-Karīm al-Fahhād al-Shīrwānī (ca. 1180) originally wrote this *Zīj* in Arabic. It is nonextant presently. It was translated into Persian by

Shamsuddīn al-Bukhārī (Tabriz, 1295/1296), whose Greek disciple Gregory Chionides prepared in ca. 1305 in Constantinople (now Istanbul) its recension in Byzantine Greek, which is fortunately extant. David Pingree published its text with an English translation and commentary, cf. van Dalen (2004, p. 826). In fact *Zīj al-‘Alā’ī* was mentioned by Abū’l Faḍl ‘Allāmī in the list of 86 *Zīj*es given in his book: *Ā’in-i Akbarī*, i.e., it was extant in the sixteenth century in India. However, Abū’l Faḍl named the compiler as Fakhruddīn Abu’l Ḥasan ‘Alī bin Karīm al-Shīrwānī, also known as al-Fahhād.

Zij-i Jāmī ‘Maḥmūd Shāh Khiljī (ZJ)

This *Zīj* is dedicated to Sultan Maḥmūd Shāh Khiljī (r. 1435–1469) of Mālwa province. This anonymous *Zīj* was written during 1448–462 because of the interruptions of the author’s travels from Cairo to Bīdar in India. An incomplete but unique manuscript copy is extant in the Bodleian Library (Oxford), Ms. Greaves 6, with 104 folios (Persian Mss. No. 1522 in the *Catalogue* by Ethé), scribed by Mawlānā Fiṭr in AH 878 (AD 1473). The Persian text of the manuscript is not complete, for it ends with the first chapter. The second chapter and the epilogue are missing. The colophon is written at the end of the first chapter. John Greaves (1602–1652), Savilian Professor of Astronomy (1643–1648) at Oxford, translated into Latin an excerpt – first section (*faṣl*) of the first chapter of the Persian text – in his *Astronomica quaedam* (London, 1650). Cf. de Young (2004), for all details about John Greaves and his work.

This *Zīj* comprises a prolegomena (*Muqaddama*), two chapters, and an epilogue (*Khātimah*). The *Muqaddama* is further divided into 36 sections (*faṣl*), in which the author deals with arithmetic, astronomical mathematics, calendars, and astrolabes. Thereafter sections contain astronomical material: treating the Sun and Moon planets and calculating their ephemerides (*Taqwīm*).

Observatory at Balāghāt

During the rule of the Khiljī’s sultans (1288–1321), practical astronomy became quite

popular because of its astrological usage. The historian Ḍiyāuddīn Barnī reported in his famous *History of Firoz Shah (Sīrat-i Fīrūz Shāhī)* that:

In Delhi the science of astrology [*‘Ilm-i Nujūm*] was very much in vogue and it was supported by the nobility and scholarly circles. ... No locality was without an astrologer [*Munajjim*]. ... The astrologers of ‘Allā’ī era [i.e., of ‘Allā’uddīn Khiljī and his descendants] were great experts and specialists of the astrological calculations and also in the astronomical observations [*raṣadbandī*]. (Ghori & Khan, 1969, p. 28) quotes Barnī’s text, p. 162.

Fīrūz Shāh Bahmanī (r. 1397–1422), the eighth sultan of the Bahmani dynasty of Deccan, was reported to have been quite an expert in several sciences, particularly in natural philosophy, logic, mathematics, and astronomy. He used to lecture 3 days a week on standard treatises of mathematics and astronomy: recension of “Principle of Euclid Geometry” (*Tahrīr Usūl Uqlidis*) by Naṣīruddīn Ṭūsī (d. 1274) and on a commentary of his “Memoirs on Astronomy” (*Tadhkira fī ‘Ilm al-Ha’ya*). However, the sultan’s interest in astronomy culminated in commissioning the first observatory on Indian soil at Bālāghāt – the summit of the pass near the Indian town of Daulatābad. The construction started in 1407 AD, i.e., before Ulugh Beg’s observatory at Samarqand in 1420 AD. However, it remained incomplete due to the sudden death of the Director-Designate Ḥakīm Ḥasan Jīlānī (Farishtah/Briggs, Vol. II, p. 27).

Zijes of the Mughal Period

Zij-Ulugh Bég (ZUB)

As mentioned above (section “Introduction to Islamic Astronomy”), the original astrolabe of Sultan Ulugh Bég’s observatory at Samarqand was a gift from the Shāh ‘Abbās I of Iran to the Mughal Emperor Jahāngīr s/o Akbar. Another noteworthy gift by the Shah was a large ruby inscribed with the name of Ulugh Bég, which was presented to the then crown prince Shāhjahān by the Iranian ambassador in about 1620–1621 (Riazul Islam, 1970, p. 80). Sultan Ulugh Bég’s madrasa and observatory, founded in Samarqand

in 1417 and 1420, respectively, were known in Mughal India. Emperor Babur visited the observatory and described it in his Memoirs (*Bābur Nāmah*). The director of the madrasa, Ṣalāḥuddīn Mūsā Qāḍī Zādeh al-Rūmī's writings are extant today in Indian manuscript collections (Ansari, 1995, Appendix, p. 292). However, the main proponent of the astronomical tables compiled at Samarqand, ZUB, was Mīr Faṭḥullāh Shīrāzī (d. 1589), a pupil of Ghiyāthuddīn al-Manṣūr Shīrāzī (d. 1506) who wrote a tract on the "Rectification (*Taṣḥīḥ*) of Zīj-i Ulugh Beg." Mīr Faṭḥullāh, who also drew the horoscope of Akbar and has been known as the inventor of Akbar's Ilāhī calendar, had been commissioned by the emperor to get ZUB translated into Sanskrit by a team of Muslim and Hindu astronomers (Abū'l Faḍl/Blochmann (Tr.), Part I, p. 110). A unique manuscript of the Sanskrit translation is extant in Maharaja Man Singh II City Palace Library (Jaipur). The importance of ZUB lies in the fact that all its tabulated material is based on actual observations. Cf. van Dalen (2007a, pp. 97–100).

According to my own survey, more than 50 copies of ZUB are available in manuscript collections/libraries of India and Pakistan (Ansari, 1995, p. 293). This is surely the indicator of the spread of ZUB. It is therefore not surprising that Zījes compiled in Mughal India were based more or less on ZUB, in style and even in content. I enumerate them in the following.

Mulla Chānd's Commentary on ZUB

Mullā Chānd ibn Bahā'uddīn was the astrologer-astronomer at Emperor Humāyūn's and later also at Akbar's courts. He is known to have drawn horoscopes of Akbar (b. 25 Oct. 1542 AD) and of Jahāngīr (b. 30 Aug. 1569); see the reproduction in Abū'l Faḍl's *Akbarnāma*, Vol. 1 (pp. 56–57) and Vol. 2 (pp. 506–507), respectively. On Akbar's horoscopes and their historical significance, see Orthmann (2005). I thank her for presenting me a copy of her publication.

A unique copy of his commentary, rather a simplified version (*Taṣḥīl*) of ZUB, is extant in the Man Singh Museum Library (Jaipur), Ms. No. 6 (Arabic and Persian). This manuscript copy

bears the seal of one 'Abd al-Khāliq ("a slave of Shāh Jahān"), dated AH 1038/AD 1628–1629. This *Taṣḥīl* by Mullā Chānd is mentioned by Farīduddīn in his *Zīj-i Shāh Jahānī* and also by Raja Jai Singh in *Zīj-i Muḥammad Shāhī*. Mullā Chānd has more or less followed the style of ZUB in the text of his commentary. He has inserted a chapter or two here and there for making the contents easily understandable. At the end of each *maqāla*, he added tables, which are updated versions of the corresponding tables of the ZUB, because of the passage of time of about 150 years between the compilation of the original ZUB and *Taṣḥīl*. Cf. Ghorī (1985, pp. 33–34).

Zījes Compiled by Farīduddīn Munajjim

Farīduddīn Mas'ūd bin Ḥāfiẓ Ibrāhīm Dehlavī, known also as Farīduddīn Munajjim (astronomer), attended the famous madrasa of Shāh Nizām of Nārnol and was also a pupil of Faṭḥullāh Shīrāzī from whom he learned rational sciences ('*Ulūm-i 'Aqliya*) including astronomy and astrology. His elder brother Ṭayyab Muhandis was also a famous mathematician, who wrote on calendars and made an astrolabe for Mirzā 'Abdul Raḥīm Khān-i Khānān (d. 1627), Emperor Akbar's Chief of Army Staff (*Sipāh Sālār*), and who became renowned as a scholar and translator of Babur's Memoirs (*Tūzak-i Bābarī*) from Turkish into Persian in 1590. Farīduddīn became well known when he prepared the horoscope of the son (b. 1613) of Sultan Ibrāhīm 'Ādil Shāh II (ruler of Bījāpūr, r. 1580–1627), the manuscript of which is extant in Berlin. Farīd began his career in the service of Khān-i Khānān and remained with him till about 1615. Three of his astronomical writings are known today: a manual on astronomical calculations, *Sirājul Istikhrāj* written in AH 1006/AD 1598, and *Zīj-i Raḥīmī* written in 1617. In 1598 he joined the service of Khān-i Khānān. The title is a chronogram, but adding only the numerical values of its dotted letters: *j* (3) + *t* (400) + *kh* (600) + *j* (3) = 1006, according to *abjad* notation. Both these works are dedicated to his patron Khān-i Khānān. The third is *Zīj-i Shāhjahānī*, compiled about 1629 and dedicated to Emperor Shāhjahān. I confine myself here only to these two Zījes.

Zij-i Raḥīmī (ZR)

The unique copy of ZR is extant in the Central Library of the Holy Shrine of Raḍawī, Ms. No. 5554 with 441 folios (cf. Fikrat's *Catalogue*, p. 299), but the manuscript is incomplete. It ends after the few tables of the planet Saturn, with no colophon evidently. As Farīd tabulates the equation of time (*Ta'dīl al-Ayyām*) for the Sun and Moon for the year 1026 AH/1617 AD (ff. 152b, 153a), he might have been compiling ZR around that year.

ZR is modeled on ZUB; it comprises an introduction (*muqaddimah*) and four discourses (*maqālas*). Farīduddīn eulogizes “the nearest of his times, the most trustworthy and accurate *Zij-i Raṣadī* compiled by Mirzā Ulugh Beg” (fol. 2b, line 7–9). Farīd distinguishes here two kinds of Zijes: *Zij-i Raṣadī* based on theoretical principles and practical observations of the positions of stars and their motions in longitude and latitude. On the other hand, *Zij-i Ḥisābī* is one of those Zijes which are corrected by calculating the discrepancies and changes occurring during the course of time in the mean motions of Sun, Moon and planets. In fact, ZR contains a section on each calendar/era as usual in Zijes, viz., Hijrī, Philip, Persian (Yazdigird), Malikī, Chinese (*Qatā*), and Chinese-Uighur. It consists also of detailed tables of trigonometrical functions (ff. 21–39), tables for solar declination (*mayl awwal*) and second declination (*mayl thānī*), and for right and oblique ascensions. The last ones are for the latitudes of Samarqand, the Indian capital town Akbarābād (modern Agra), and for Lahore. Farīduddīn included also in his Zij a geographical gazetteer of 325 cities. Cf. Ansari (2013, section 3.2).

Zij-i Shāhjahānī (ZShJ)

It was completed in AH 1039/AD 1629, but the epoch year is AH 1041/AD 1631–1632. Farīduddīn compiled this Zij in collaboration with his brother Ṭayyab and under the supervision of Yamīn al-Dawlah Āṣaf Khān. As the title indicates the Zij is dedicated to Shāhjahān. The complete title is *Kārnamah-i Ṣāhib Qirān-i Thānī, Zij-i Shāhjahānī* (Great Work of the Lord of Second Conjunction, Shāhjahān's Zij). This ceremonious title owes its origin to the fact

that Venus and Jupiter were in conjunction (*Qiran*) at the time of Shāhjahān's birth on 5 Jan. 1592 in Lahore. R. C. Kapoor (Bangalore) has checked this statement by calculating for 00:00 UT the elliptical longitudes of Venus and Jupiter at the time of birth of Shāhjahān. They are 8 s 15°.1290 and 8 s 3°.4112, respectively, i.e., both in the same zodiac sign Scorpio. I thank Kapoor for this assistance. Exactly the same conjunction occurred at the birth of Amīr Tīmūr, the great great grand forefather of Shāhjahān. Therefore Tīmūr and Shāhjahān were entitled as “Lord (*Ṣāhib*) of the first and second conjunctions (*Qiran*).” Actually this is an astrologically auspicious conjunction. ‘Abdul Ḥamīd Lāhorī, the emperor's chronicler in his *Pāḍshāh Nāmāh*, reported that “in view of its many benefits and [containing] numerous principles and rules, [the Emperor] ordered that it should be translated into the language of Hindustan by Indian astronomers in consultation with Persian astronomers for the sake of public utility” (Ṭāhir/‘Ināyat Khān, *Mulakhkhaṣ* p. 82). In fact Pandit Nityānanda, the Hindu court astronomer of Shāhjahān, translated the ZShJ into Sanskrit in 1630. Four copies of this text with the title *Siddhāntasindhu* are extant in the Maharajah Man Singh Museum and Royal Collection in Jaipur.

The ZShJ consists of the same chapters as in ZUB, i.e., one introduction and four discourses (*maqālas*). Each *maqāla* is divided into many chapters (*bāb*); a chapter is further divided into sections (*qism* or *faṣl*). The introduction is similar to Farīduddīn's ZR, defining and explaining *Zij-i Raṣadī* and *Zij-i Ḥisābī*. The chapter on calendar/eras comprises the usual Hijrī, Rūmī, Yazdigird, Malikī, and Chinese-Uighur, but with the addition of the Indian calendar, *Shākhā Sālbāhan* (*Śālivāhana Śākha* in Sanskrit). The tables of ZShJ are not confined to the basic tables but contain auxiliary tables for simplification, as in ZR or in any commentary. For technical details cf. van Dalen (2007a), p.148.

Zij-i Muḥammad Shāhī (ZMS)

Sawā'i Jai Singh (1688–1743), raja of Amber (modern Rajasthan), was an erudite scholar of

Sanskrit literature and particularly of astronomy. He wished to implement his program of improving ancient and medieval Indian astronomy. To that end he is known to found a number of observatories with masonry instruments. These astronomical observatories were built in five Indian cities, namely, Delhi (1721–1724), Jaipur (1728–1735), Banaras (~1730), Ujjain (~1730), and Mathura (year unknown), so that observations of the same phenomenon could be carried out from many locations. As he was extremely receptive to astronomical ideas of different cultural areas, he established a school of translations at Jaipur for translation of Islamic astronomical treatises into Sanskrit (Sarma, 1998) and later also European scientific texts, especially Philippe de La Hire's *astronomical tables* and Homann's *Atlas*. Johann Baptist Homann's *Grosser Atlas über die Ganze Welt* (Nürnberg 1725), acquired in 1730, is preserved in the Sawai Man Singh Museum (Jaipur). This Atlas is important, since it contains charts for the planetary systems of Copernicus, Tycho Brahe, and Riccioli. These were brought to Sawā'i Jai Singh by his delegation of Indian astronomers sent to the Portuguese King, which was headed by Jesuit Emmanuel de Figueiredo; the delegation returned in Nov. 1730. What immortalized Jai Singh's name throughout the world of astronomy was in fact the *Zīj-i Muḥammad Shāhī*. In fact Emperor Muhammad Shāh (r. 1719–1748) on the advice of his astrologer, Mubashshir Khān, directed Sawai Jai Singh to get a modern (*Jadīd*) Zīj compiled, so that the actual title is *Zīj-i Jadīd Muḥammad Shāhī*. Various sections in ZMS are based solely on *Zīj-i Ulugh Bég*. The tables and texts concern the Sun, Moon, and planetary mean motions adapted from de La Hire's tables. See details in Mercier (1984), van Dalen (2000), and Pingree (2002). ZMS became quite popular among the Persian-knowing Indian scholars (14 mss. extant in India), also in Iran (32 mss.) and Central Asia (13 mss.), where it almost replaced the *Zīj-i Ulugh Bég*. The earliest extant manuscript copy to date is in Tashkent and is scribed by Ḥuḍūr Ilāhī Kāshmīrī, dated 1775.

Sawai Jai Singh mentioned in one chapter of ZMS that he had a telescope constructed in his kingdom and used it for observing the crescent of Venus, satellites of Jupiter, rings of Saturn, and sunspots. Ansari (1985a) has discussed the diagrams of these observations, which appear on the margin of a couple of manuscripts of ZMS. However for want of micrometer and cross-wire attachments, he could not use them as devices for accurate measurements (Ansari, 1985b, pp. 364–369).

According to a number of Persian sources, Mirzā Khayrullāh Khān (d. 1747), director of Jai Singh's observatory at Delhi, was the actual compiler of ZMS, who was supervised by Jai Singh. Muḥammad 'Alī s/o Khayrullāh Khān, who scribed a copy of ZMS (Ms. 2144, fol. 105A, in the National Library, Tehran), confirmed his father's authorship of ZMS. Another evidence is from Iranian commentator, Muḥammad 'Alī alias Mubashshir Khān, who came to India to study under Khayrullāh Khān the text of ZMS and its method of calculations. His commentary on ZMS is extant in the National Library, Tehran (Ms. No. 6447, scribed in 1884). See details in Ansari (2007/2014).

Zīj-i Bahādurkhānī (ZBK_h)

This Zīj in Persian was composed in 1838 by Abul Qāsim alias Ghulām Ḥusain Jaunpūrī, on the order of the Rāja Khān Bahādur Khān, the raja of Tikārī (in south of Bihar), to whom it was dedicated. This Zīj was written in India between 1855 and 1858 and lithographed at the Cadre (*Kādar*) Press, Banaras (modern Varanasi). The printed copy is extant in the Salar Jung Museum Library (Hyderabad). It consists of 906 pages of about quarto size. A good copy of *Zīj-i Bahādurkhānī* is also extant in the Andhra Pradesh Oriental Manuscripts Library (Hyderabad). A recent facsimile reprint of ZBK_h was published in 2009 by Islamic Azad University (*Dānishgāh-i Āzād Islāmī*), Tehran, with a preface by Farid Ghassemlou. ZBK_h is actually a reworking of ZMS based on Ghulām Ḥusain's own observations, in which especially the new elements of European astronomical knowledge were included and explained.

Zij-i Sa'īdī by Muḥammad Amīn (ZS)

The author Muḥammad Amīn Mas'ūdī bin Muḥammad Nasīm al-Ḥanafī with the *nom de plume* Kāshī came from the Indian city of Bareilly. To date only this much is known about him. The Zij is dedicated presumably to his patron Sa'īd. A unique copy of this Zij is extant in the Wellcome Library (London), scribed in AH 1244/AD 1828 (at colophon fol. 51b), with author's name as Muḥammad Amīn Mas'ūdī. However, his full name on fol. 1a, line 7-8, is as mentioned above but without Amīn. The manuscript was discovered by van Dalen (2007a, p. 150). I thank him for a copy of this manuscript.

ZS consists of an introduction with three discourses (*maqāla*) and an epilogue. In the section on the calendar, he treats Hijri, Yazdigird, Jalālī, Byzantine (*Rūmī*), the Chinese (*Khaṭā*), and Turkish eras. Muḥammad Amīn has drawn actually on *Zij-i Ulugh Bég*, which is his basic source even for the calculation of ephemerides of the Sun, Moon, planets, etc. His sections are quite short. While calculating the position of the constellation Cassiopeia, he mentions using ZMS and the year 737 Jalālī/AD 1815 (fol. 26a). His source for the astrological material is Ptolemy, Māshā'allāh (d. ca. 815), and Ya'qūb al-Kindī (d. 870) (fol. 48a). The section on gazetteer (ff. 17–18) contains entries of 311 localities, out of which 70 are Indian cities and interestingly the last entry is London.

Zij-i Mazhari (ZM)

The author is Mazharuddīn Muḥammad Qārī bin Bahā'uddīn 'Alī (sixteenth century) Shīrāzī. The manuscript of this Zij belonged to the Urdu Promotion Board (*Anjuman Taraqqi-i Urdu*), Karachi. It was originally in the collection of Mawlawī 'Abdul Ḥaq (Hyderabad), who presented it to the Urdu Promotion Board. It is now in the National Museum (Karachi). Monzavi (Cat. Ms. No. 493, pp. 278–279) has given some historical information about the author. However, this is the first time that the contents are being described here. I thank Mr. Rashid Ashraf (Karachi) for procuring for me the copy of this unique manuscript. It is dated AH 987/AD 1579 (fly leaf/f. 1a). It has 33 ff. The first two pages are missing, since

the manuscript begins abruptly with the sixth section (*faṣl*) of the contents. Altogether there are 12 sections (*faṣl*). The last is on fixed stars, which is not present in this manuscript.

The first part of ZM is on usual astronomical calculations according to *Zij-i Ulugh Bég* (mentioned specifically on f. 4b), as an aid to the second part on astrology which is concerned with determining various astrological parameters. The epilogue (*khātma*) begins with the “invisible and inauspicious [actually pseudo-planet] *Kaid* (f. 32a) and calculation of its ephemerides in the year 929 Yazdigird/AD 1560” (f. 33a), determination of planetary exaltation (*sharaf*), and dejection or depression (*hubūf*). Our author's source for this part is mainly Ptolemy's *Tetrabiblos*. Some examples to illustrate the rules are dated 1558, 1560, and 1565. I thank Mr. Rashid Ashraf (Karachi) to arrange for me a copy of this unique manuscript.

Astrolabe Makers in India

In the Sultanate period, Sultan Fīrūz Shāh Tughlaq (r. 1351–1388) was famous as an expert on astrolabes. Astrolabes used for both Northern and Southern celestial hemispheres are attributed to him. Fīrūz Shāh possessed five astrolabes constructed under his guidance. They were one each in brass and silver, in gold and silver, in brass only, and two in silver. A large Northern-Southern astrolabe in gold and silver was named *Asturlāb-i Fīrūz Shāhī*, which was completed by AH 771/AD 1370–1371. In the text of *Sīrat-i Fīrūz Shāhī*, positions of constellations for the period 1370–1520 equivalent to 136 lunar years are also tabulated. This table was engraved on the back of Fīrūz's astrolabe. Moreover, the coordinates of 18 fixed stars are marked on the *rete* corresponding to 11 March 1370 (Sarma, 1998, pp. 9–10). However, Fīrūz Shāh's most significant achievement was actually “the dissemination of the science of astrolabe in India among the Jains and Hindus” (Sarma, 1998, p. 12). The Sultan's court astronomer, the Jaina scholar Mahendra Sūrī, composed the first ever treatise on the astrolabe in Sanskrit: *Yantrarāja* (the King

Astronomy in Medieval India, Table 1 Astrolabes by Alāhadād's descendants

Number of specimens	Astrolabe maker	(Period of activity)	Current location	Year of manufacture
3	Mullā 'Īsā s/o Alāhadād		Two in Chicago; one in Cambridge (UK)	1601, 1604
6	Qā'im Muḥammad s/o 'Īsā		Calcutta	1624
			Patna	1626
			Baghdad	1631
			Oxford	1634
32	Diyā'uddīn s/o Qā'im	(1645–1680)	In India: two formerly in Aligarh	1653, 1663
			Hyderabad, Patna	
			Three in Jaipur observatory	
37	Muḥammad Muqīm, s/o 'Īsā	(fl. 1609–1659)	In India: two in Delhi	1624
			Calcutta, Hyderabad. In Pakistan: Lahore, Karachi	1637
12	Hāmid s/o Muqīm	(1628–1691)	One in Hyderabad	1658
			One in Allahabad	1677
5	Jamāluddīn s/o Muqīm	(1666–1691)	None in India	

Note: The specimens are mostly in museums. Sarma (formerly at Aligarh Muslim University and now in Düsseldorf) is compiling a worldwide *Catalogue of Astrolabes made in India* by (see “Ghulam Hussain Jaunpūrī”) Indian astrolabe makers. I thank him for putting at my disposal his data before his monumental publication

of Instruments) written about 1370. The importance of this text is indicated by the fact that there are extant 100 manuscript copies (Ohashi, 1997, p. 211 et seq. and Sarma, 1999, 2000).

Lahore School of Astrolabe Makers

The founder of the Lahore school of astrolabe makers was the famous Ustād Alāhadād Aṣṭurlābī Humāyūnī (flourished ca. 1567) who had been invited to Lahore by Mughal Emperor Humāyūn; the emperor was himself an expert on the astrolabe; main reference to this section is Sarma (1994) and Ansari (2011). One of Alāhadād's two surviving astrolabes is in Salar Jung Museum (Hyderabad) dated 1567 with a diameter of the *mater* (main body) of 199 mm, containing five latitude plates (tympan) and with a gazetteer (geographical coordinates) of 96 cities. The second astrolabe is extant in the Museum of History of Science (Oxford). It is not dated, and its diameter is 256 mm with six disks and a gazetteer of 157 cities. In the following, I tabulate the work of the descendants of Alāhadād.

According to S. R. Sarma (*personal communication*, dated 11 May 2010), “there are extant nearly 120 astrolabes signed by the various

members of the Lahore family, and several more which are not signed but can be attributed to the family on stylistic grounds.” The Lahore school of Alāhadād also made celestial globes; 23 are extant today (Sarma, 1994, p. 219). For astrolabes with Sanskrit legends made in medieval India, cf. Sarma (1999) and Ansari (2011) (Table 1).

Conclusion

My effort has been to delineate the efforts of promoting in Medieval India the Islamic astronomy as developed in the Middle East and Central Asia. The practical astronomy – compiling Zīj, establishing observatories and a school of astrolabe makers – developed because the individual astronomers and madrasas were patronized by sultans, emperors, local rulers, and nobles. Even modern European astronomy of the eighteenth to nineteenth century was well received; cf. Ansari (2002) in which a few sources in Persian have been discussed. The political upheaval due to the colonization of India by European powers during the eighteenth to nineteenth centuries led to the

withdrawal of patronization, marginalizing the madrasas, the institutions of higher education, which were the lifeline for the development of mathematics and astronomy, thereby smothering the scientific renaissance initiated by Raja Sawa'i Jai Singh in the eighteenth century. The compulsory replacement of Arabic and Persian by English as medium of instructions cut off the continuity of India's education and scientific development during the Raj. Thanks to independence, that situation was reversed. Modern India is now playing its role in the world to develop astronomy and space science quite actively.

Astronomy in Mesoamerica

Michael J. Grofe

American River College, Sacramento, CA, USA

Astronomy in Mesoamerica developed in apparent isolation from the cultural traditions outside of the Americas and its unique advancement provides an important comparison with parallel developments of astronomical science elsewhere in the world. Containing hundreds of distinct ethnic groups and indigenous languages, the Mesoamerican culture area extends south from central Mexico into Belize, Guatemala, Honduras, El Salvador, and Nicaragua. While highly diverse, many of the cultures and language groups in this region share innovations such as intensive maize agriculture, stratified urban development, megalithic architecture, and an elaborate calendrical system consisting of a unique, repeating cycle of 260 days and a cycle of 365 days that estimates the length of the year. Together, these cycles combine to form the 52-year Calendar Round, historically shared by more than 50 linguistic groups in Mesoamerica.

It is clear that the development of writing in Mesoamerica was deeply interwoven with calendrical and astronomical observations that were

Astronomy in Mesoamerica,

Fig. 1 Uaxactun E-Group, ideally commemorating rising azimuth positions of the solstices, and the equinoxes (Drawing by author)

themselves inseparable from religious, divinatory, and political interests. Having persisted for perhaps 2,000 years, much of this intellectual legacy did not survive the initial invasion of the Spanish and the subsequent decimation of indigenous populations as a result of violence, disease, and centuries of political and religious persecution. Indigenous writing systems were effectively extinguished, and many written records did not survive. However, recognizable astronomical traditions have endured in many communities.

What is currently known about Mesoamerican astronomy has been reconstructed from architectural alignments, surviving written texts, and the persistence of astronomical and calendrical knowledge among contemporary indigenous groups. While it remains difficult to reconstruct and reinterpret the full extent of Mesoamerican astronomy from fragmentary sources, the existence of explicit written sources as well as implied astronomical alignments and ethnographic evidence has led to a more solid consensus among researchers, while there still remain specific areas of controversy.

It is generally agreed that Mesoamerican architectural alignments commemorate repeating celestial observations of horizon-based azimuth positions. Most obvious and familiar among these are those that suggest references to the rising and setting positions of the sun on the solstices and equinoxes. Multiple so-called “E-Group” building configurations in the Maya lowlands, such as

those first identified in Uaxactun (Fig. 1), generally commemorate solstitial alignments, though the actual precision of these alignments is questionable and they may have served additional astronomical, calendrical, and ritual functions (Aimers & Rice, 2006). While the equinoctial alignments of E-Groups appear to be much less certain, a functional east-west sight line does appear at the northern Maya site of Dzibilchaltun.

Unique to the tropics, the phenomenon of the two solar zenith passages appears to have provided Mesoamericans with a precise means to calculate the length of the tropical year and to predict the seasonal rains that follow the zeniths through the migrating intertropical convergence zone. The early ethnographic record demonstrates that the observation of the solar zenith was widespread in Mesoamerica, and these days were attended with religious celebrations that were a concern to the Spanish crown (Aveni, 2001, p. 42). Contemporary Ch’orti farmers continue to predict the solar zeniths through observing the rising and setting azimuths of the sun on the 2 days when the sun reaches the zenith, and these positions actually replace the cardinal directions of east and west. According to anthropologist Raphael Girard, the Ch’orti also observe the relative positions of the Pleiades, Orion’s belt, and the Southern Cross in order to predict the occurrence of the two zeniths.

At different latitudes in the tropics, the two solar zeniths occur on different dates separated by

Astronomy in Mesoamerica, Fig. 2 Idealized zenith tube, commemorating the two solar zenith passages (Drawing by author)

variable intervals that are equidistant from the solstices. Several scholars, including Zelia Nuttall, Vincent Malmström, and Raphael Girard, have suggested that the unusual 260-day calendar found only in Mesoamerica arose in Preclassic sites to commemorate the long interval between the two zenith passages at 14.8° North latitude, namely, on August 12–13 and on April 30 to May 1. If so, it then would have spread northward throughout Mesoamerica into latitudes where the two zeniths would be at very different intervals. This astronomical explanation differs from the more widely held indigenous belief that the interval arose as a means to calculate the length of human gestation. Nevertheless, these proposals may not be mutually exclusive.

Vertical tubes that would be useful for observing solar zeniths are evident in several sites throughout Mesoamerica, including Monte Alban, Xochicalco, and Chichen Itza. These consist of subterranean chambers located beneath vertical tubes that connect to a narrow oculus (Fig. 2). At the moment of the solar zeniths, dramatic beams of light shine vertically through the oculus and into the chamber below. Though none of the surviving zenith tubes are located at 14.8° N, another similar structure in Teotihuacan with a wider oculus

appears to commemorate not the local zeniths but the fixed cycle of 260 days between August 13 and May 1. In fact, as Malmström points out, the entire layout of the city of Teotihuacan, including the Temple of the Sun, is oriented toward sunset on August 13 and May 1, again implicating this fixed cycle, and we find similar architectural alignments and hierophanies to this fixed cycle throughout Mesoamerica.

The zenith tube located in Building P in Monte Alban is curiously associated with a direct line of sight to Building J (Fig. 3), an arrow-shaped building that is offset from the layout of the city. While some have proposed that the back side of the arrow intended to align with the rising of Capella in association with the zenith in the second century BC, the arrow actually points quite precisely to the base of the Milky Way in the southwest when it reached its vertical position at dawn at the time of the May zenith in the Preclassic. As such, this recognition of the vertical Milky Way parallels known contemporary observations among the Ch'orti and Tzotzil.

We also learn from Girard that the Ch'orti commemorate the solar nadir or anti-zenith in February, while Barbara Tedlock reports that K'iche' astronomers determine that the solar nadirs correspond to the time of year when the full moon reaches the zenith. The Ch'orti, who live precisely in the zone where the two zeniths are 260 days apart, do maintain a fixed cycle of 260 days that follows the agricultural year, though this begins on the February solar nadir and ends on the solar nadir in late October. Similarly, in a survey of 23 Late Preclassic and Classic structures in Campeche, Mexico, Ivan Sprajc (2009) has determined consistent alignments to sunrise on February 12 and October 30 that clearly delimit the agricultural year at multiple latitudes.

As Alonso Mendez, Edwin Barnhart, Christopher Powell, and Carol Karasik demonstrate, the Temple of the Sun in Palenque contains multiple alignments to hierophanies on the solar nadirs, the solar zeniths, and the summer solstice. Architectural alignments to local zeniths and nadirs are likewise evident in both the Caracol (Fig. 4) and the Castillo (Fig. 5) at Chichen Itza. While popular interpretations of the hierophany of the

shadow of the descending feathered serpents on the Castillo have assumed that this structure intended to commemorate the equinoxes, Susan Milbrath (1988) demonstrates that the east-west axis is more precisely aligned to the local zenith passages and solar nadirs. At the same time, the vertically descending serpents with their rattles pointing toward the zenith (Fig. 6) immediately recall the Pleiades, known to contemporary Yucatec observers as *tzab*, a rattlesnake’s rattle. The Pleiades crossed the zenith at the latitude of

Chichen Itza at the time of the construction of the Castillo, and it would have been heliacally rising at the time of the local zenith in late May, which announced the arrival of the rains. Indeed, contemporary Maya farmers continue to use the disappearance and reappearance of the Pleiades to time the planting of maize. In its descent, the feathered serpent of the Castillo evokes similar diving gods, which Nuttall believes to be representative of both the zenith and the time of planting.

Astronomy in Mesoamerica, Fig. 6 Rattle of descending serpent pointing toward zenith, Temple of the Jaguars, Chichen Itza (Photograph by author)

The Caracol in Chichen Itza was constructed in the shape of a round turret, and buildings like this are known to be associated with Ehecatl-Quetzalcoatl, an Avatar of Venus. Along with its alignment to zeniths, the Caracol shows significant alignments with the northern and

southern extremes of Venus, and similar Venus alignments have been proposed for Temple 22 in Copán (Closs, Aveni, & Crowley 1984). As Sprajc demonstrates, the House of the Governor at Uxmal contains numerous iconographic references to Venus, while it also aligns to the setting positions of Venus at its northerly extreme. While not a yearly phenomenon, this northerly extreme would correspond with the onset of the rainy season, and the symbolic association between Venus and fertility is evident.

Unfortunately, without clear associations to text references, the intentionality of architectural alignments is difficult to verify. Therefore, astronomical references in the written record are particularly significant, and these are most explicit in Maya hieroglyphic records. Recognizable Venus glyphs appear in the Preclassic Maya site of San Bartolo in iconographic association with named deities (Fig. 7), while two important text references to Venus appear in the early La Mojarra Stela, a non-Maya monument written in the Isthmian script and dated to the second century AD (Kaufman & Justeson, 2001).

Surprisingly few hieroglyphic text references to Venus appear in the Classic period inscriptions. Copán Temple 11 records a Venus event similar to those found in the Postclassic Dresden Codex Venus Table, while multiple scholars have proposed that various other historical dates intended to commemorate the appearances of Venus at various points in its cycle, among

Astronomy in Mesoamerica, Fig. 7 San Bartolo Mural, showing Venus glyph in *upper left*, second from last, along with Venus deity in bloodletting scene. other astronomical rationales. Such arguments were quite popular in the earlier days of the decipherment, since the emphasis on astronomical interpretations was popularized by their prevalence in the few extant Maya hieroglyphic codices, the calendrical and astronomical significance of which was deciphered long before the historical content of the inscriptions was recognized. As a reaction to this overemphasis on astronomy, subsequent historical interpretations have often chosen to overlook problematic astronomical references.

There are only four surviving Maya screenfold books, all of which contain astronomical information, including widely acknowledged references to constellations, lunar synodic cycles, eclipses, and planetary cycles. The Paris Codex

contains an apparent “zodiac” of 13 distinct constellations shown in association with eclipse glyphs, including a scorpion that is curiously in the same position as Scorpius (Fig. 8). However, it is debated whether these figures represent a true zodiac, given that a turtle constellation may represent Orion, which is south of the ecliptic. The Dresden Codex contains the most extensive astronomical information, including a Venus Table (Fig. 9) consisting of a canonical 584-day synodic cycle divided into 5 cycles of 584 days, equivalent to 8 cycles of the 365-day year, effectively returning the heliacal rise of Venus to the same time of year. This table is recycled for 104 years, which then commensurates with the 260-day cycle, and calendrical data associated with the table demonstrate that additional corrections would enable variously proposed calculations of the heliacal rise of Venus over much longer periods of time. Various other tables in the Dresden Codex suggest other planetary cycles. Tables of 780 days in the Dresden Codex suggest the synodic cycle of Mars, while Anthony Aveni and Harvey and Victoria Bricker have proposed that another table in the Dresden Codex was used to calculate the sidereal cycle of Mars.

We find similar Venus almanacs in the codices from Central Mexico, such as those from the Borgia group, though none quite as explicit as that found in the Dresden Codex. Nevertheless, several scholars, including Victoria Bricker and Susan Milbrath, have variously attempted to correlate the tables and the imagery in the Borgia Codex with specific astronomical events, such as historical eclipses, appearances of Venus, and seasonal configurations of stars. While it is difficult to verify the astronomical intention of these narrative scenes without explicit dates, we do find such unambiguous dates in association with Maya inscriptions. However, even fixing these more explicit dates in time remains somewhat problematic and controversial, let alone interpreting the intent of their associated inscriptions.

In addition to the Calendar Round found throughout Mesoamerica, a chronological system known as the Long Count first appeared in the

Astronomy in Mesoamerica, Fig. 8 The Paris Codex “Zodiac.” Scorpion at the *left*; turtle in the *center*; rattlesnake at the *right*. Each devours (or stings) the glyph for a

solar eclipse beneath a Sky Band, representing the ecliptic (Drawing by author after FAMSI photograph)

Preclassic and spread throughout the Maya area where it was ubiquitously used on monuments throughout the Classic period. This largely vigesimal positional system functioned as a precise count of days and 360-day periods reckoned from a back-calculated base date over 3,000 years prior to the first evidence of the use of this system. In this respect, the Long Count resembles the Julian Day Number (JDN) system used by contemporary astronomers to count the number of days elapsed from January 1, 4713 BC. As such, the Long Count was extremely useful as a means by which to calculate and record astronomical observations over long periods of time.

Long Count dates are typically given together with the 260-day cycle as well as the 365-day cycle (Fig. 10), and these interwoven cycles were remarkably continuous and unadjusted, though some examples of slightly offset Calendar Rounds do occur. However, it is more difficult to assess whether the Long Count itself was ever corrected or shifted from its original count, and many scholars have assumed that it remained unbroken. Various attempts to correlate the Long Count with the Julian and Gregorian calendars have often used assumed astronomical references to support their correlations, yet these

approaches have proven to be problematic if only one their assumptions is incorrect.

Utilizing several ethnohistorical references to Calendar Round and K’atun positions – along with contemporary and historical 260-day counts maintained by living Maya calendar keepers – John Goodman, Juan Martínez Hernández, and Eric Thompson provided the original proposals which have resulted in the two most widely used correlations that match the Era base date of the Long Count with two different Julian Day Numbers (584283 and 584285). These are collectively known as the GMT correlation constants, and there is still disagreement among scholars regarding which is more accurate, though astronomical data strongly supports both. Given some of the unresolved discrepancies, some scholars maintain that neither correlation is correct, calling into question any proposed astronomical references that result from these correlations.

Goodman first noted that the Long Count Initial Series dates are often given together with what he named the Supplementary Series, and John Teeple first demonstrated that Glyphs D and E of this series record the age of the moon as measured from various points near the

Astronomy in Mesoamerica, Fig. 9 Dresden Codex Venus Table. Dresden Codex, page 49. Photograph Licensed under Public domain via Wikimedia Commons – http://commons.wikimedia.org/wiki/File:Dresden_codex,_page_2.jpg#mediaviewer/File:Dresden_codex,_page_2.jpg

new moon, while Glyph A designates a lunar month of either 29 or 30 days in length – the alternation of which closely corresponds with the true synodic lunar month of 29.53059 days. As a whole, lunar data from the Supplementary Series strongly supports *both* of the GMT correlations while it does not appear to favor either

one, since it is unclear exactly on which day Maya observers were recording the first day of the new moon. Significantly, the lunar data from the Classic period inscriptions is consistent with that from the Lunar Table found in the Dresden Codex, and one run of this table corresponds with 11,960 days, which is equivalent to 46 cycles of 260 days and 46 synodic lunar months of 29.5308642 days. Teeple found that this exact same value for the synodic lunar cycle was used in Classic period Palenque to back-calculate lunar data for precise mythological dates found in the Cross Group. Indeed, a recently discovered series of painted texts from a wall in Xultun provides clear evidence for an earlier precedent for the Dresden Lunar Table in the Classic period.

The Dresden Lunar Table also significantly includes important eclipse data that closely corresponds with the eclipse year when using either of the two GMT correlation constants, and Harvey and Victoria Bricker (1983) have shown that the table could be used to determine repeating eclipse “warning stations,” whether or not actual historical eclipses were visible. Surprisingly, overt references to eclipses are extremely rare throughout the Classic period inscriptions, with the exception of one recognizable reference on Poco Uinic Stela 3. First noticed by Teeple, this reference shows a solar eclipse glyph similar to those found in the codices, and it is associated with the Long Count date 9.17.19.13.16. A near total eclipse is known to have occurred just after noon at Poco Uinic on JDN 2009802, which corresponds with July 16, 790 AD. Therefore, Simon Martin and Joel Skidmore (2012) conclude that the correct correlation should place the Era base on JDN 584286, one day forward from one of the GMT correlations. However, Vincent Malmström (1999) maintains that the 584285 GMT correlation can be reconciled with the Poco Uinic eclipse, given that the Maya day began and ended at sunset. Therefore, the Long Count may actually overlap two Julian days, which begin and end at noon Greenwich Mean Time or sunrise in the Maya area. The Poco Uinic eclipse lends some support to the 584285 GMT correlation, while it would not support the competing 584283 correlation. Given that the

Astronomy in Mesoamerica,

Fig. 10 Maya Initial Series from Quirigua Stela J. Long Count, 260-day Tzolk'in and 365-day Haab, along with Supplementary Series, showing lunar information (Drawing after Matthew Looper in Grofe (2011a))

260-day count preserved by the Highland Maya supports the latter, it is apparent that a shift of the 260-day cycle may have occurred at some time in the Postclassic, after the Long Count fell out of use.

Establishing the validity of the Long Count correlation holds great promise in that it provides the ability to observe specific, historical astronomical patterns and potential intentions in association with hieroglyphic texts and architectural alignments. Given that the 584285 GMT correlation places the Era base of the Long Count on August 13, 3114 BC Gregorian (September 8, Julian), both Robert Merrill and Vincent Malmström proposed that the Long Count Era

base corresponds to the August 13 zenith passage at 14.8° N latitude where the two zeniths are precisely 260 days apart. Such a precise correspondence not only implies an intentional and highly accurate calculation of the tropical year but also suggests the means by which such a calculation could have been performed using the solar zenith. If the originators of the Long Count did in fact make such a calculation, it would follow that, at the time of the earliest attested Long Count date from Chiapa de Corzo in 36 BC, Mesoamericans had already achieved a measurement of the tropical year that was unsurpassed until Johannes Kepler in 1627. For some, such a bold assertion may be difficult to

accept without additional supporting evidence. Therefore, it is all the more important to investigate this question further with a great deal of scrutiny.

Based on evidence from Copán Stela A, Teeple deduced that the drift of the 365-day Haab from alignment with the tropical year would have provided for a highly accurate tropical year of 365.2419355 days, derived from the equation of $1,403,990 \text{ days} = 3,844 \text{ tropical years}$ and slightly more accurate than the Gregorian year of 365.2425 days. Using this so-called determinant theory, Teeple and Thompson identified various values for the tropical year in different sites at different times. However, this theory lost favor when it was later determined that the dates used refer to historical events in the lives of Maya rulers. Nevertheless, the intentional association of such historical events with astronomical underpinnings should not be overlooked.

Indeed, Maya inscriptions in the Classic and Postclassic contain many long-distance numbers that link specific historical events with contrived, back-calculated mythological events that suggest astronomical measurements. Several of these dates imply tropical year calculations that apparently targeted the canonical February nadir at 14.8° N . This is visible in the base date for the Dresden Venus Table, Copán Stela C, the Palenque Temple of the Foliated Cross, and Naranjo Altar 1. In addition, historical commemoration of both actual and canonical February nadirs is apparent in multiple inscriptions, particularly as a common date for the accession of kings in Copán, Tortuguero, and Naranjo (Grofe, 2011b).

Analysis of the back-calculated February 8, 310 BC canonical nadir from Naranjo Altar 1 also reveals that it would have placed the sun at a lunar node during the heliacal rise of Venus and in precisely the same sidereal position in which it historically appeared 304,263 days later, the interval given by the distance number. This suggests that Maya astronomers were able to calculate the sidereal year, since 304,624 days is very nearly a whole multiple of 834 sidereal years. The value for the sidereal year here results in 365.2553957 days, while the actual current

value is 365.25636 days. Evidence for this kind of sidereal year calculation has also been proposed within the immense distance numbers from the Serpent Series in the Dresden Codex that exceed 15,000 and 30,000 years. Similar calculations are apparent in Copán Stela J, Tortuguero Monument 6, and in the Palenque Temple of the Inscriptions and Temple of the Cross (Grofe, 2007, 2011b). Like proposed measurements of the tropical year, these proposals remain controversial, and it is not entirely clear from the evidence whether these measurements of the sidereal year were distinguished from the measurement of the tropical year. Certainly, making such a distinction would indicate that Maya astronomers were well aware of the precession of the equinoxes, a proposal that finds some support in the 3–11 Pik title (Grofe, 2003, 2011a; MacLeod, 2008). Given to Maya kings who have reached an advanced age, the 3–11 Pik title represents a 33 Bak'tun cycle, or 13,200 cycles of 360 days, approximating one-half of a precessional cycle of some 26,000 years. A bone from Burial 116 in Tikal indicates that this count began on the Era base, while an inscription from the Caracol in Chichen Itza suggests that another cycle was completed on the Era base. Together, these two cycles comprise a full cycle of precession. Additionally, a smaller interpretation of the same Calendar Round reached by this larger interval is equivalent to 25,980 days, approximating 1 day of precessional drift between the sidereal year and tropical year.

Further analyses of numerous distance numbers from the Maya hieroglyphic inscriptions and codices promise to either reveal or refute the intentionality of proposed astronomical calculations and patterns and the potential significance of their associated texts. A more complete, interdisciplinary understanding of the capabilities of Mesoamerican astronomers likewise requires a more fully developed exploration of the religious and political motivations of these observations and the persistence of astronomical knowledge that has endured as a living tradition. The unique features of Mesoamerican astronomy necessitate that scholars be aware of the tendency to incorrectly attribute their own motivations to peoples

quite different from themselves. While remaining rigorously skeptical and open to what the evidence does or does not reveal, it is equally important and enlivening to recognize our shared humanity and the structural similarities that are evident in the historical development of widely separated astronomical traditions.

Astronomy in Native North America

Edwin C. Krupp

Griffith Observatory, Los Angeles, CA, USA

Introduction

The astronomical activities and traditions of the American Indians north of Mexico were based upon practical observation of the sky but were not supported by a written language. For that reason, our knowledge of North American Indian astronomy relies upon the archaeological data, ethno-historic reports from early encounters between Europeans and the indigenous peoples, and ethnographic information collected more recently by anthropologists. Although this material is distorted and incomplete, it enables us to outline the general character of North American Indian

astronomy and to understand some of it in detail. All of these sources confirm that North American Indians farmed, hunted, and gathered by the sky. They developed calendric techniques to order the sacred and ordinary dimensions of their lives. They timed ceremonies by the sky. They extracted symbols from the sky. They told stories about the sky. Throughout all of the cultural territories, physical environments, and linguistic traditions of North America, celestial phenomena were incorporated into ritual, iconography, myth, shamanic activity, and worldview (Krupp 1978, 1983, 1984, 1991, 1996).

North American Indians were familiar, of course, with the fundamental cycle of day and night, the daytime path of the sun, and the unmoving pole of the night sky. Cardinal directions, which emerge from the daily rotation of the sky and the circular parade in which the stars march at night, were important to many groups. The moon's phases were monitored, and each monthly cycle was often associated with a seasonal change on earth. The seasonal shift of sunrise, sunset, and the sun's daily path was known. Solstices were recognized, and the rising and setting points of the summer and winter solstice sun sometimes established an alternate directional scheme. Seasonal appearances and disappearances of stars were noted. Constellations were contrived from conspicuous and useful stars. In the historic era, unusual events like eclipses, bright comets, fireballs, and meteor showers attracted notice and sometimes provoked ritual response. Planets were recognized by at least some groups, but explicit evidence of detailed indigenous knowledge of their cyclical behavior has not survived (Williamson 1984).

Like traditional peoples everywhere, the Indians of North America saw the sky as a realm of power. Access to that power required knowledge of the sky. They acquired that knowledge through careful observation and used that knowledge to order and stabilize their lives. This practical understanding of the sky – the sun, the moon, and the stars – is not the same thing as modern scientific astronomy, for it did not attempt to test and abandon metaphors of nature in the same way science does today. It did,

however, help integrate human behavior with nature and consolidate social cohesion. Celestial objects were not just convenient metronomes. They were powerful, supernatural beings, and they revealed the basic structure – the fundamental order of the world. Because cosmic order is, in part, what is meant by the sacred, the Indians' interaction with the sky was an encounter with the sacred.

Main Text

The earliest account of North American Indian astronomy was reported in 1524 by the Italian explorer Giovanni di ve Verrazzano (Wroth 1970). He encountered the Narragansett Indians of Rhode Island and mentioned that their seeding and cultivation of legumes were guided by the moon and the rising of the Pleiades (Ceci 1978). The Pleiades comprise a distinctive cluster of stars. Its value as a signal of seasonal change was recognized throughout the continent. In California, for example, there is explicit evidence of Pleiades lore in all but 12 of the 58 native cultural territories. Those 12 actually correspond to a very small fraction of the entire area and population of the state, and their lack of Pleiades tradition is primarily due to linguistic and cultural extinction. Despite the extraordinary linguistic diversity represented by the 75 mutually unintelligible California Indian languages and 300 different dialects, names for the Pleiades, myths about the Pleiades, and seasonal references to the Pleiades are documented in all five major families of indigenous California languages.

Studies of North American Indian astronomy have emphasized the prehistoric Southwest and the historic Pueblos (Malville & Putnam 1989). This is due to the survival of Ancestral Pueblo architectural monuments and rock art and to the preservation of some information about historic Pueblo astronomical techniques and celestial lore in ethnological reports. Close to the end of the last century, Stephen (1936) described in detail the horizon calendar used by the Hopi Sun Chief to establish key dates in the ceremonial and agricultural cycles of the village of Walpi. More

recently, historian of science McCluskey (1977) demonstrated that Hopi observations of the sun were accurate to 4 arcmin. This is, however, an average error, and it is difficult to do much better than 30 arcmin in any single horizon event. McCluskey verified that the Hopi actually allowed themselves a few days' leeway in scheduling the winter solstice ceremony.

If Stephen had not seen the Sun Chief perform his duties, we would not know where his sunwatching station was located. Nothing marks the point out at the end of a mesa or on the roof of the highest house. Other references to North American horizon observatories suggest that many were just as subtly blended into the community landscape, and that makes the identification of prehistoric observatories a challenge. Symbolic astronomy was, however, often incorporated into monumental architecture and rock art. By analyzing alignments and iconography, it is sometimes possible to spot the hand of the ancient skywatcher. For example, Pueblo Bonito, an 800-room, five-story, D-shaped apartment-town in Chaco Canyon, New Mexico, makes good use of passive solar heating to stabilize room temperatures in summer and winter. It was completed in the twelfth century AD, and its east–west front wall is oriented cardinally with an accuracy of 8 arcmin. Such accuracy is achievable with simple surveying techniques that rely upon the unaided eye, but it is nevertheless respectable. In addition, archaeologist Jonathan Reyman interpreted corner windows in two rooms as winter solstice sunrise apertures (Krupp 1978; Williamson 1984).

The Ancestral Pueblo built large subterranean community ceremonial chambers known as Great Kivas. Most of these, like Chaco Canyon's Casa Rinconada, possess cardinal orientation, and the plan of a Great Kiva is thought to mirror the Pueblo concept of the cosmos.

There are many pictographs and petroglyphs in Chaco Canyon, and the star and crescent on a panel near the Penasco Blanco ruin have been promoted by some as a representation of the AD 1054 Crab supernova explosion. Prehistoric Indians in the American Southwest very likely saw that spectacular event, but there is no way to

verify that the Penasco Blanco pictographs are an eyewitness record of it. The supernova interpretation of star/crescent elements in Southwest rock art was first offered in 1955 as an explanation for two sites in northern Arizona. Since then, the number of reported star/crescent groupings has multiplied, but opinion on the supernova is divided. Reyman argues thoughtfully that the Penasco Blanco site is actually a sunwatcher's shrine and implies that the Crab supernova has nothing to do with these star/crescent designs. Even if they do depict the supernova rising with the waning crescent moon on the morning of 5 July 1054, they tell us nothing substantive about Ancestral Pueblo astronomy. In 1990, Robbins and Westmoreland (1991) revived the argument all over again with an analysis of numerical symbolism on prehistoric Mimbres ceramics. One of these has a rabbit in the shape of a crescent moon accompanied by a "star" with 23 rays. This detail is argued to be consistent with the Chinese historical account of the Crab supernova, for the Chinese reported it was visible in the daytime for 23 days.

A spiral petroglyph on Fajada Butte, the most conspicuous landmark in Chaco Canyon, interacts with "daggers" of midday sunlight at the solstices and the equinoxes. These light-and-shadow effects, first reported by Sofaer et al. (1979), received a great deal of international attention and inspired considerable controversy. Initially, the "Anasazi Sun Dagger" was interpreted as a "precise solar marker," but it may be more correct to regard it as a symbolic seasonal display.

One of the best candidates for a sunwatcher's observing platform is also located in Chaco Canyon, on an upper ledge on a rincon (a square-cut recess or hollow in a cliff) near Wijiji ruin. Rock art on the ledge includes elements as old as the Ancestral Pueblo and as recent as the Navajo. A line-of-sight to the southeast coincides with a natural rock chimney on the other side of the rincon, and this feature dramatically marks the winter solstice sunrise.

Astronomer Zeilik has emphasized the importance of "anticipatory" observations of the solstices and other astronomical events (Zeilik 1985).

The Sun Chief must know ahead of time, with accuracy, when the solstice is due in order to mobilize the community for the ceremonial activity that culminates in the solstice. This is exactly what Walpi's Sun Chief did, and Wijiji has the ability to deliver advance information and confirmation of the solstice. The site is interpreted, then, by extending significant information from the historic period back into the prehistoric context.

Astronomical components have been identified at many other sites in the Southwest, including Hovenweep, Yellow Jacket, Chimney Rock, Casa Grande, and Mesa Verde (Malville 1991). Celestial rock art elements are present throughout the Southwest. Few of these involve accurate mapping of constellations, but several seem to invoke magical power attributed to the stars. Chamberlain (1989) has studied Navajo star ceilings in Canyon de Chelly and concluded that most of them are connected with symbolic protection or other celestial magic. Schaafsma (1990) interprets war and star imagery in the petroglyphs of New Mexico's Galisteo Basin as part of a tradition of Southern Tewa celestial war magic.

Nine years after astronomer Hawkins (1963) rekindled interest in ancient and prehistoric astronomy in 1963, with his studies of solar and lunar astronomical alignments in Stonehenge, another astronomer, Eddy (1984), identified celestial sightlines in the Bighorn Medicine Wheel, a North American antiquity *Time* magazine headlined as "Stonehenge USA." The Bighorn Medicine Wheel is located at an elevation of 9,600 ft, above the timberline on Wyoming's Medicine Mountain. It is a ring, 87 ft in diameter, drawn in small rocks. Originally, the Wheel had 27 or 28 spokes of stones that converged on the main cairn at the center. Five other cairns were constructed on the Wheel's rim, and the one spoke that extends beyond the rim ends in its own cairn. The ring is actually a flattened circle. Its axis of symmetry coincides with the spoke that reaches from the outside cairn, southwest of the rim, to the cairn at the center. Eddy demonstrated that this line also continues to the northeast horizon and the point of summer solstice sunrise.

He associated other lines between cairns with the sequential risings of three bright stars in the predawn sky in summer. Although the age of the Bighorn Medicine Wheel is uncertain, a radiocarbon date for a piece of wood retrieved from the central cairn associates it with the seventeenth century. Eddy thought that the Bighorn Medicine Wheel might have been used at that time by historic Plains Indians to make astronomical observations.

It seems likely, however, that the Bighorn Medicine Wheel is much older. It resembles other similar structures, especially in southern Canada, that are known to be thousands of years old. Who built the Bighorn Medicine Wheel and when it was built are still not known with certainty. There is reason to be skeptical about the practical value and validity of the stellar alignments, but the summer solstice sunrise line is congruent with the design. If the solstice alignment were part of the original plan, it may have had as much to do with vision quests and shamanic retreat as with calendric observation.

In the historic era, Plains Indians incorporated the sky into symbols and ritual. The well-known Sun Dance was intended to inspire prayer and visions through self-infliction of pain, fasting, and thirst. Gazing at the sun while suspended from a pole with ropes looped through the flesh of the chest was thought to purify and spiritually strengthen the participant. Although not all Plains tribes practiced this demanding regimen in the Sun Dance, acquisition of sacred power was a common theme. The enclosure in which the ceremony took place is called a Sun Dance Lodge, and it is sometimes built with 28 posts said to represent the days of the lunar month. Originally, the ritual was performed at the time of the summer full moon nearest to the time of the bison hunt.

Another Plains group, the Skidi band of the Pawnee, is known to have possessed a rich and detailed tradition of star lore. This knowledge has been reviewed and analyzed by Chamberlain (1982) in *When the Stars Came Down to Earth*. The Skidi Pawnee Morning Star sacrifice was timed by the movements of planets,

especially Mars and Venus, and mythologically, the planets were key players in the Skidi Pawnee Creation myth.

In Nebraska, the Omaha devised a symbol of social cohesion and tribal stability out of the Sacred Pole that was erected ceremonially at tribal gatherings. Omaha myth and ritual allow us to deduce that the Sacred Pole was oriented on the north celestial pole. Its power was linked to the stabilizing character of the hub of the sky.

It is a curious fact that so much public interest in ancient North American Indian astronomy has been directed toward the prehistoric Southwest and the Bighorn Medicine Wheel. Although these sites are valid targets of study, they belong to relatively unpopulated parts of the continent. Even the well-documented traditions of the Plains Sun Dance, the Skidi Pawnee Morning Star Sacrifice, and polar axis symbolism of the Omaha Sacred Pole must be considered marginal traditions of North America.

The mainstream, on the other hand, belongs to the most populated zones of North America. To understand, then, the true character of North American Indian astronomy, it is necessary to look at the Mississippi Valley and California. Nowhere north of Mesoamerica had a comparable population density.

Unfortunately, we know relatively little about the astronomical traditions of the ancient Mississippi Valley. In 1961, however, archaeologist Wittry (1973) excavated a feature he called the Sun Circle at Cahokia, a great population center and powerhouse of regional trade in central Illinois between AD 700 and 1200. Cahokia is best known for its large mounds, some of which supported temples and residences. Others hosted burials. Monks Mound, the largest prehistoric earthen construction in the world, is the centerpiece of what was the Chicago of the prehistoric Midwest.

Originally, the Sun Circle was a 410-foot-diameter ring of 48 tall posts (perhaps 30 ft high), with a pole in the middle of the circle but offset apparently intentionally 5 ft from the true center. Three of the posts that once occupied the holes that now remain combined with the center pole to deliver alignments to the rising sun at

summer solstice, winter solstice, and the equinoxes. Wittry believed that the Sun Circle's purpose was calendric. It is difficult to understand, however, why a complete ring of posts would be needed and why the posts were so tall. On the other hand, the intentional displacement of the central post makes the astronomical alignments possible.

Despite the ambiguity that persists with Cahokia's Sun Circle, archaeologist Fowler verified the ancient Cahokians' interest in cardinal directions. The city's limits were established by a particular type of earthen mound, and these mounds also defined the primary, and cardinal, axes of the site. In 1994, Fowler described another post circle on the main north-south axis of Cahokia. Its design, size, and astronomical potential mimic the Sun Circle.

The Incinerator Site, a smaller stockaded Mississippian village near Dayton, Ohio, included an arrangement of posts also thought to have astronomical meaning. The largest post, 2 ft in diameter, was located in a plaza, and it formed a line with a post inside a nearby building. This line pointed to the sunrise on April 24 and August 20. Both dates potentially have agricultural significance. The April date could mark the end of the frost and the beginning of planting. The August date is linked to the Green Corn Ritual, performed in the historic era when the corn filled the husk but was not yet ripe. Cardinaly oriented logs were kindled at this time into the New Fire, which also had solar associations.

European explorers encountered the descendants of the Mississippian mound builders in the southeast United States. The chief of the Natchez was known as the Great Sun. He claimed to be the brother of the sun and greeted the sun each morning, when it first appeared from the top of his residence mound. We also know the Natchez subdivided the daylight hours into four periods based upon the position of the sun. They measured the year in months based on the observed phases of the moon and named each lunation for an appropriate seasonal phenomenon.

In the Far West, before Columbus, California competed respectably with the Mississippi

Valley for the distinction of being the most populous and densely populated zone north of Mesoamerica. Some indigenous astronomical traditions persisted in California until quite late, and valuable information was collected by ethnographers, especially Harrington. The revival of interest in California Indian astronomy was largely initiated by Hudson and Underhay (1978), whose book, *Crystals in the Sky*, reconstructed the sky lore of southern California's Chumash Indians. Explicit references to horizon observations of the solstice sun and solstice rituals have been collected from the entire state. The moon's phases were counted, and the lunar months were named by most California groups. They recognized familiar patterns of stars, including the Big Dipper and the Belt of Orion. They named many other stars and used them as seasonal signals. They saw the Milky Way as a route to the sky followed by the souls of the deceased. Elaborate Milky Way ceremonialism is known among the Luiseño, who incorporated it into ritual initiation of the youth, mourning songs for the dead, sacred myth, and rock art.

California possesses many rock art sites and some of the most complex rock art in the world. Some of these sites have been associated with solstitial light-and-shadow events that interact with the rock art. Often, particularly at winter solstice, the light develops into a pointed, knife-like shape that pierces a carved or painted element. These effects appear to be symbolic, for they do not generally pinpoint the solstice with high accuracy. Rather, they "work" over a solstice "season" perhaps 2–4 weeks long. Although there is no explicit evidence that links solstice effects with California rock art, we do know the names of two Chumash shamans who went into the mountains at the time of winter solstice to paint on the rocks.

Conclusion

In detailed application, Native American astronomy was richly varied in North America, but its purpose and basic character were broadly the

same throughout the continent. For that reason, we can rely upon Francisco Patencio, Chief of the Palm Springs Indians of southern California, for words that could apply to nearly all Indians:

When the sun swung to the north and the moon showed quartered by day overhead, or west, they knew by the signs of the sun and the moon when the seeds of certain plants were ripe, and they got ready to go away and gather the harvest. Every plant that grew, the nesting time of all birds, the time of the young eagles, everything they learned by the signs of the sun and the moon. *Stories and Legends of the Palm Springs Indians* (Los Angeles: Times Mirror, 1943).

Astronomy in Sub-Saharan Africa

Keith Snedegar

At the turn of a new millennium the study of astronomical practices in precolonial African societies remains an open field. Major sources of evidence have yet to be fully scrutinized – astronomical texts in Arabic, Ge'ez, Hausa, Malagasy and Swahili, celestial

iconography in the African arts, and perhaps most importantly, astronomical knowledge encoded in the vast reservoir of oral tradition. It should be no surprise that Muusa Galaal's groundbreaking monograph on Somali ethnoastronomy derives wholly from oral literature (Galaal, 1992). As for the built environment, a few African architectural structures have been surveyed for astronomically meaningful features with interesting if not definitive results; further archaeoastronomical research would doubtless reveal more about the cosmologies behind African material culture. Nonetheless, scholars from various disciplines have already demonstrated that African time reckoning, divination systems, performance art and literature utilized the sky as a cultural resource. Jarita Holbrook of the University of Arizona is a leader of a new generation of scholars exploring African cultural astronomy (Holbrook, 2004, 2005). At a popular level the documentary film *Cosmic Africa* (2003), featuring the South African astronomer Thebe Medupe, has done much to introduce the subject to wider audiences.

Sahara Region

Ancient astronomically aligned structures have been discovered in a megalithic complex in the southern Egyptian desert at Nabta, where nomadic pastoralists made their summer camps by a playa, or seasonal lake, between 6,500 and 5,300 years ago. The Nabta site probably served as a ceremonial center. It comprises several oval clusters of stones and isolated megaliths, and numerous tumuli containing cattle and sheep burials. The burials are analogous with ritual practices of modern African pastoralists who slaughter animals to mark socially important occasions. Archaeoastronomer McKim Malville used theodolite and GPS measurements to map the site. He found three lines of megaliths radiating from the largest structure. A nearby stone circle containing four sets of upright slabs, which may have been used to fix positions along the horizon, exhibits two line-of-sight "windows," along a north-south axis and at an azimuth

of 62°; the rising mid-summer sun would have been visible through the second line of sight circa 6,000 years ago. Malville has theorized that the geometry of the standing stones reifies a conceptual system integrating death, water, seasonal fertility, and the motion of the sun (Malville, McKim, Wendorf, Mazar, & Schild, 1998). Presumably, the ancient Nabtans correlated solstice observations with the onset of summer monsoon rains. It is intriguing that the megaliths, located in the playa deposits, would have stood in the shallow lake water. The rising and falling water level marked against the stones could have been a powerful indicator of seasonality. With climatic change bringing hyperaridity and desertification to the Sahara region around 4,800 years ago, the seasonal occupation of Nabta came to an end. The Nabtan pastoralists may have migrated to the Nile Valley, contributing their practice of solar observation as well as their reverence for cattle to the cultural development of predynastic Egypt (Wendorf & Schild, 2001).

While Nabta is the earliest Saharan site thought to have astronomical alignments, surveys of pre-Islamic tombs in the Tassili N'Ajjer region of Algeria and parts of southern Morocco have also indicated structural orientations suggestive of some calendrical purpose (Belmonte et al., 1999, 2002). In the historic period the nomadic Tuareg people have practiced celestial navigation in their travels across the great desert. When traveling north the Tuareg oriented themselves according to the mother camel constellation *Talamt* (Ursa Major), and when traveling south they watched the gazelle stars *Ineren* (α and β Centauri). *Əmanar*, "The Guide" (Orion) and *Tələzdak*, the date palm (Scorpius) are other important asterisms in the Tuareg sky (Donaint, 1975).

West Africa

By the first millennium AD the trade between West Africa and Mediterranean North Africa was functioning as an important mechanism for cultural exchange. The transmission of Islam to West Africa would engender formal academic

traditions based on written texts in Arabic. From the fifteenth century onward a number of scholars in Timbuktu and other Islamic centers studied astronomy as an adjunct to the Quranic sciences. The corpus of Arabic scientific writings of West African provenance has yet to be analyzed in any detail, but a number of manuscripts preserve meteorological observations, particularly floodings of the Niger River, and details of solar and lunar calendars (Saad, 1983). Rebstock (1990) located numerous mathematical, astronomical and astrological texts in Mauretania, 13 of them having to do with the Islamic calendar. Results of a study by the Al Furqan Foundation suggest that roughly 1 % of Arabic manuscripts in West Africa contain astronomical material (Hunwick, 1997). There are probably several hundred texts yet to be identified and analyzed. A Library of Congress exhibit of manuscripts from Timbuktu afforded a glimpse of this raw material, including tracts entitled *The Important Stars among the Multitude of the Heavens* and *The Rise and Setting of Auspicious Stars* (Library of Congress, 2003).

The existence of these texts indicates that at least some West African scholars engaged Arabic mathematical astronomy at rather advanced level. However, the reputed fascination of Aḥmad Bābā al-Tinbuki (1556–1627) and al-ḥājj Muḥammad al-'Iraqi (fl. 1650) with esoteric astrology likely typifies the chief matter of interest. Many West African literati dabbled in celestial divination; others considered astrological prediction spiritually dangerous. The great Fulani scholar Muḥammad al-Wali (d.1688) wrote a diatribe against astrology and its practitioners. Ironically, his pupil Muḥammad ibn Muḥammad gained fame with an astrological opus, *al-Durr al-Manzūm* (Strung Pearls). It was not an original work. Its chief source was the *Secret Concerning the Dialogue with the Stars* of the Persian sage, Fakhr al-Dīn ► *al-Rāzī* (Ullmann, 1972). The lack of any coherent school of astronomy or astrology in West Africa is perhaps attested by Muḥammad Bello of Sokoto, who recorded his observations of a bright comet in 1825. Several people asked him to explain the phenomenon so he wrote a treatise on it. Unable

to find any scientific writings on comets, he was reduced to quoting theological opinions to assure his readers that the object did not signify the end of the world (Ogunbiyi, 1991–1992) (Fig. 1).

The science of the stars did not remain solely in the Arabic language. Savants in the city of Kano translated Arabic star lore into Hausa. The anonymous pedagogical text, *Hisabi 'Assawwakai*, gives an elementary account of Islamic astronomy, and is still circulating in northern Nigeria (Kani, 1992). The Hausa took up astrology with enthusiasm, astrological verse becoming a prominent genre of vernacular literature. A Hausa poem attributed to Abdullah ibn Muḥammad describes the 28 *anwā*, 12 signs of the Zodiac, and planetary rulership of parts of the sky, according to the foreign practice. Ibn Muḥammad apparently learned his astrological theory from the writings of Moroccan practitioners such as 'Abd al-Hāqq, whose *Kitāb al-falak* (Book of the Planets), was widely read in Northern Nigeria. While the Ibn Muḥammad text largely retains Arabic terminology, other Hausa works apply indigenous epithets for the stars which were not derivations from the Arabic but reflect local tradition (Hiskett, 1967, 1975).

As for the built environment in West Africa, studies by Drucker-Brown (1984) and Blier (1987) have shown that certain vernacular architectures perform a symbolic as well as a functional purpose; home design not only manages light and heat resources but incorporates visual metaphors of directional affiliation and spatial organization alluding to the sun's diurnal and annual motion. Among the Mamprusi of northern Ghana the *zonga* or entranceway of one's home faces west so that the rays of the setting sun are directed into an area where family elders sit. It is here where in the late afternoon the position of light falling onto a wall is judged as an indication of the agricultural seasons. Elaborating on this theme, the Batammaliba people of Togo and Benin believe that the home should be representative of the solar deity, Kuiye. When a house is constructed, the builders perform a ritual in hour of Kuiye. It occurs at local noon when the sun is on the meridian, the "center" of the sky, and

Astronomy in

Sub-Saharan Africa,

A

involves the placement of cooked cereal on the *tabote* stone in the center of the homestead. The home itself is aligned on an east-west axis, with its portal and family shrines facing west. This allows the rays of the setting sun to strike the shrines of the family's deceased elders; it is believed that when such shrines are illuminated, Kuiye communicates with the ancestors about the affairs of living family members. Batammaliba granaries are also identified with Kuiye's domain, being divided into three sections, each associated with a different crop harvested in accordance with the three seasons delimited by tradition (Fig. 2).

Unfortunately, while West African astronomical traditions have not as a whole attracted much attention, an inordinate amount of publicity has surrounded exaggerated claims for an advanced state of knowledge on the part of the Dogon

people of Mali. Based on their fieldwork conducted in the 1930s, Griaule and Dieterlen (1950, 1965) reported that the Dogon were aware of Sirius B, a small star invisible to the unaided eye. Such was the fuel for Temple (1975), among others, who claimed for the Dogon a heliocentric model of the solar system and independent knowledge of the satellites of Jupiter and the rings of Saturn. Thanks to television series such as "In Search of . . ." (1979) the Dogon have entered the popular imagination. Penetrating criticism by respected scientists and a field evaluation of Griaule's reportage, determining many elements, including the astronomical portions, to be either misconstrued or altogether unsupported by ethnographic evidence, have done little to stay the proliferation of misinformation on Dogon cosmology (Van Beek, 1991).

East Africa and Madagascar

By the shores of Lake Turkana a megalithic site designated ► [Namoratunga II](#), comprising 19 basalt pillars and at least one grave marked by upright slabs, has been surveyed for possible astronomical alignments (Lynch & Robbins, 1978). Although there is no proof positive that the Namoratunga stones were erected with an observational purpose in mind, they appear to be nonrandomly aligned in directions corresponding with the rising positions of seven conspicuous stars and asterisms – Bellatrix, Orion's Belt (δ , ϵ , ζ Orionis), Saiph, Sirius, the Pleiades, Aldebaran, and Triangulum – on the local horizon ca. 300 BCE. These stars may have served as calendrical markers for the ancient Cushitic people who erected Namoratunga. However, efforts to elucidate a cultural linkage

between the purported Namoratunga tradition and calendrical practices of the Borana people in the historical period have met with doubtful results (Soper, 1982; Doyle & Wilcox, 1986). Most scholars have identified the Borana asterism *Lami* as the constellation Triangulum, but when Tablino (1994) asked Borana time-reckoning experts to identify *Lami* they invariably pointed out α and β Arietis. The Triangulum alignment at Namoratunga, at least, looks to be questionable.

Christian Ethiopia has a tradition of skywatching documented in manuscripts dated back to the Middle Ages. Neugebauer (1979, 1981) found that Ethiopian astronomical knowledge applied almost exclusively in religious contexts. The astronomical chapters of the Ethiopic *Book of Enoch* contain simple arithmetical schemes for the motion of the sun and moon. The origins of this treatment are obscure, but

they are more likely to derive from the rudimentary astronomical traditions of Egyptian Judeo-Christian communities than from early Babylonian schemes. Other texts and Easter tables of the Ethiopian Church reflect the computus of Alexandrian Christianity. A thirteenth-century computus of Abu Shaker of Alexandria, for reckoning Easter and other movable feasts, is extant in a number of Ethiopic manuscripts dating from the sixteenth century. Ethiopian chronicles record comets, eclipses, and other astronomical events from the fifteenth century onward.

The folk astronomy of Islamic Somalia appears to be directly influenced by the practices of south Arabia. Nomadic Somali herders know Polaris as *Hhiddigo*, the Prayer Star; by noting its direction after establishing an evening camp, they can orient themselves toward Mecca for their five daily prayers. Somalis have also adopted the 7 day week, and the folk practice of *taawil*, or assigning a good or evil value to each day. The most telling indicator of Arabic influence, however, is the recognition of lunar stations (Arabic: *anwā'*), 28 stars or asterisms, noted for their risings and settings over the year. Although the camel and sheep herding peoples of Somali used the *anwā'* (called *god* in Somali dialects) as a framework for a seasonal calendar, they viewed lunar stations primarily as divinatory signifiers. It is still held by many Somalis that the Moon's passage through the stations releases favorable or unfavorable celestial influence. *Dirir* (Spica) which means "good omen" is the most important station, as it is believed to govern the summer rains. Traditional Somali weather experts judge the quantity of future rain when *Dirir* is in conjunction with the Moon; a majority consider the Moon and *Dirir* rising in conjunction to be an auspicious sign. However, if the Moon passes north of *Dirir* a drought is expected. A child born on the night of a conjunction is thought to possess *buruud*, the ability to inspire respect among the people. A *Dirir* child will also have good fortune in owning camels and horses. At all events, a considerable body of Somali proverbs, songs and folktales has grown around the import of lunar stations (Galaal, 1992).

Peoples of the East African coast have for centuries engaged in long distance trade with the Middle East and South Asia. The fifteenth-century master seafarer Aḥmad ▶ *ibn Mājid* left behind an Arabic memoir on Indian Ocean navigation techniques which relied heavily on stellar observation. He noted that navigators of Mombasa, Sofala, and Madagascar sailed by the stars of Ursa Major, which they called *al-Hīrāb* (Tibbetts, 1981). Swahili manuscripts at the University of Dar es Salaam also attest to celestial navigation on the part of East Africans. The Arabic element was considerable nonetheless: a majority of the 105 Swahili star names collected by Knappert (1993) are derived from Arabic, and Kiswahili lunar station vocabulary preserves the Arabic terminology essentially unaltered. Moreover, the adoption of Islam by Swahili-speaking peoples brought with it the Islamic lunar calendar and the practice of orienting mosques in the direction of Mecca. Nonetheless, the Swahili lived in an environment of parallel time-reckoning systems. The indigenous Bantu tradition of the Pleiades or *Kilimia* remained distinct from the *anwā'* system and continued to be used for the regulation of agricultural work. In Swahili the Pleiades are *Kilimia*, the Ploughing Stars. Referring to the *vuli* and *masika* monsoon periods, and their respective planting seasons, a proverb runs: "If the Ploughing Stars set in sunny weather they rise in rain, if they set in rain they rise in sunny weather." As viewed in the evenings from equatorial Africa the Pleiades disappear in the Sun's glare, they "set" about early May, reemerging in the morning sky just as June's *vuli* rains begin. Observed in the predawn sky *Kilimia* are seen to set at the end of the *masika* rains in November; when they are glimpsed rising in the evening twilight they herald a dry or "sunny" period. Alongside the Islamic lunar calendar Swahili-speaking peoples kept a 365-day year subdivided into 36 and a half "decades" of 10 days each. This solar year, which begins with the *Nairuzi* festival, appears to be of Persian origin (Gray, 1955).

On the island of Madagascar the highly syncretic *Mpandandro* astrological system appears

Astronomy in Sub-Saharan Africa, Fig. 3 Plan of a Malagasy house indicating directional associations with 12 months and 28 lunar stations (Ruud, 1960)

to integrate Arabic and South Asian practices with indigenous culture. Writing in a modified Arabic script, scholars among Antaimoro and Antambahaoka peoples of southeastern Madagascar compile *Sorabe*, or “great books” containing history, medicine, geomancy and astrology. Malagasy astrologers utilize lunar stations and assign favorable/unfavorable values to days within a 7-day week. The temporal scheme is represented spatially in the orientation and lay out of the traditional rectangular house (Verin & Rajaonarimanana, 1991) (Fig. 3).

Central and Southern Africa

The African states centered on Great Zimbabwe and Mapungubwe between the twelfth and fifteenth centuries presumably developed temporal and spatial ideologies involving the sky. Even so, there is no conclusive evidence for intentional astronomical alignments at Great Zimbabwe, despite the recent conjectures of independent archaeologist Richard Wade (Campbell, 2002). Other southern African sites have not been surveyed specifically for their archaeoastronomical

potential, but the features of an Iron Age village called Ntsuanatsatsi are very suggestive. Situated a kilometer west of a prominent hill in the grassy highveld of the Orange Free State, South Africa, the stone-walled ruins face eastward. The place name, Ntsuanatsatsi, attested to as early as the 1830s, means “sunrise” in the Sesotho language. For local Sotho clans the hill is reputed to have been where the first ancestors rose from the earth. In former times, Bafokeng chiefs held their councils on top of the ridge across from the hill. Their ability to gauge the annual motion of the sun by the sunrise locations on Ntsuanatsatsi hill may have contributed to the prominence of these early Sotho leaders (Maggs, 1976).

The ritual initiation of adolescents into full membership of the community is an important aspect of African society. A “morning star,” usually identified in the literature as the planet Venus, traditionally had strong associations with male rites of passage in Central and Southern Africa. The Mbunda people looked for an object they called *gongonosi*; the Tsonga of Mozambique used the cognate term *ngongomela* “towering in strength.” Victor Turner noted the visibility of such a morning star on the last morning of the Ndembu ceremonies he witnessed; he further recorded that the initiation title of the third boy to be circumcised was *kaselantanda*, “he of the morning star” (Turner, 1967). According to Junod (1927), Tsonga initiation schools were synchronized with the appearance of Venus in the morning sky during a winter month (June–September in the southern hemisphere). One of Junod’s informants, the Tsonga elder Shinangana, chronicled a few of the schools in the last half of the nineteenth century: they occurred in 1862, 1873, 1881, 1887, and 1893. Venus was indeed a morning star in the first 3 years, but not in 1887 or 1893, although in the later year Jupiter was located in the morning sky and could have served as *ngongomela*. Hence, it would be rash to assert any correlation between periods of the morning visibility of Venus and the age-sets of Tsonga initiates. In a praise poem which inspired the young Nelson Mandela, Krune Mqayi sang of counting the years of manhood by the rising “Morning Star.” For the Xhosa

of South Africa this object was unquestionably the Pleiades, the dawn rising of which occurs late in June. It is said that the month of the Pleiades, *Eyesilimela*, symbolized new life; the coming-out ceremony of the *abakwtha* circumcision school was synchronized with the appearance of the star cluster (Snedegar, 1997). The morning star, however imprecise its own identity, was recognized across central and southern Africa as a key identifier of the male child’s passage into the daylight of adulthood.

The night figures prominently in the cognitive universe of the Khoisan peoples, who articulate their knowledge in oral traditions which have been transmitted across generations. The evening campfire traditionally served as the venue for sky stories. Appropriately, many San groups recognize a “Fire Finisher” star whose position above the horizon indicates the time on cold winter nights. Fire Finisher is said to rise in the evening and set before dawn, about the time the night’s fire has burned to embers. By all accounts, Fire Finisher is a brilliant star which seems to be alone in the sky. Three stars fit the profile and are in fact identified as Fire Finisher by different San groups: Antares (by the Nharo), Arcturus (!Xo), and Regulus (G/wi). Like Fire Finisher, all stars are associated with fire. In the Ju/’huoan dialect the act of stoking a fire, causing sparks to fly into the air, is described with the same words as a shooting star. One of the most famous myths concerns a girl of the “early race” who created the Milky Way by throwing ashes from her campfire into the sky. For many San, however, the Milky Way is the Backbone of the Night. There may be a connection with the moon. A nineteenth-century explanation of the Moon’s waning phases claims that the Sun chases the Moon; as it catches up, the Sun slices away pieces of the Moon until nothing remains. But before the Moon is altogether devoured, it says, “Oh Sun! Leave for the children the backbone!” (Bleek & Lloyd, 1911). Sirius is often identified as the Hip Star or Thigh Star. In her fieldwork, Marshall (1986) discovered that the !Kung San see Canopus and Capella as “horns of *tshxum*,” an identity, perhaps a magical rain bull, centered on the Pleiades. Predawn observation of *tshxum* and its horns indicated the coming of spring rains.

Astronomy in Sub-Saharan Africa,

Fig. 4 San rock painting of bolide-like object near Bethlehem, South Africa (Thackeray, 1988)

In Khoisan mythology human ancestor spirits inhabit the night. They are accompanied by spirits of terrestrial animals including lions, elands, gemboks, hartebeests, steenboks, porcupines, hedgehogs, and giraffes. The starry sky becomes a great canvas for hunting stories, of which ≠Gao N!a, or G≠kao N!a'an, is often the leading man. According to a story collected by Marshall (1986), ≠Gao stood on the Large Magellanic Cloud one evening looking for game to hunt. He spotted three zebras, the three stars in Orion's Belt, and shot an arrow at the middle one. The arrow fell short; it is represented by the stars just south of the zebras. After his unsuccessful shot, ≠Gao decided to send the zebras down to earth for the San to hunt. Nineteenth-century Khoikhoi told a similar tale. Their rendition identified the hunter with the star Aldebaran, spurred on by his wives, the Pleiades. Having failed in his hunt, Aldebaran cannot return to his family, and is fixed in his place in the sky. Another story independently documented by Marshall and Biesele (1996), involves the sons of ≠Gao, !Xuma and Kha//an, identified with α and γ Crucis, who went out hunting an eland but themselves were pursued and killed by two lions "the keepers of the west," α and β Centauri. ≠Gao suspected the lions. He hid a pair of magic horns in a tree, and invited the lions to dance under its branches. The horns fell onto the celebrating lions, killing them. ≠Gao then resurrected his sons. Celestial players reenact the story on October evenings when the

stars of Crux, representing the two boys, set or "die" on the southwestern horizon; they are followed by α and β Centauri, the lions tricked into death. As viewed from San locations in the Kalahari Desert, where Crux is not quite circumpolar, α and γ Crucis rise again later in the night; the boys are visually resurrected.

Meteors have an important place in Khoisan folklore. These "shooting stars" are interpreted in various ways, but they are generally considered to signify creatures having supernatural powers. Some say meteors are antlions falling to earth in search of food; for others they are porcupines or hedgehogs. Hence a porcupine-skin bag is called a star skin, and hedgehog fat is a chief ingredient for amulets worn in curing dances (Traill, 1994). Through dance a shaman enters a trance state in which, it is believed, he is able to traverse the sky as a meteor, obtaining supernatural potency from the ancestors. Such potency is supposed to give him the mastery over disease as well as control of game animals and the spring rains. The meteoric trance experience is very probably illustrated in rock art. Although only a few rock art images suggestive of meteoric trance have been recorded, the territory in which these images have been found stretches from Zambia to Lesotho (Thackeray, 1988). One extraordinary rock painting in South Africa portrays a shamanistic dance; a bolide-like object appears to zoom over the dancers' heads and burst into two fragments (Fig. 4).

The Chaco Region

The Great Chaco region is located in central South America. It partially covers the south of

Bolivia, Paraguay, and northwest Argentina. The Argentinean portion of this region includes the provinces of Chaco and Formosa, the oriental portion of the provinces of Salta and Santiago del Estero, and the north portion of Santa Fe.

The Argentinean Chaco was inhabited by various aboriginal groups and a complex non-aboriginal population. Before the arrival of the Spaniards, the social organization of the Argentinean Chaco aboriginal groups was based on small bands. Originally most of them were hunters and gatherers. The three most prominent linguistic groups were and still are the Guaycurú, Mataco-Mataguayo, and Guaraní.

These aboriginal people underwent several changes during colonial times and had complex relationships with the colonial society. Despite the fact that they were politically independent from the colonial government, many types of exchanges between these aboriginal groups and the Creole and European population existed from trade to military conflicts.

Between the eighteenth and nineteenth centuries, numerous religious actors arrived in the area, like the Jesuits and later on the Protestant missionaries. These presences played a key role in new Indian resignifications of Christian practices and cosmologies (López, 2014a, b).

Nowadays, a population of around 133,000 original people survive by working as rural laborers and by developing a variable amount of hunting and gathering (INDEC. *Encuesta Complementaria de Pueblos Indígenas (ECPI) 2004–2005*).

Specific Groups

We will focus on two specific aboriginal groups in the region to exemplify some of the main characteristics concerning their conceptions of the sky. In the examples selected we analyze notions that are key to a large variety of Chaco groups, which indicates the relevance of exchanges in South American cosmologies, both in pre- and post-Columbian times (López, 2014a, b).

Toba of Western Formosa

The Toba (Guaycurú linguistic group) who settle in the west of the province of Formosa (Argentina) specifically reside in the Bermejo Department. Both among the Toba and other Chaco groups, the celestial sphere is mythically related to the female domain. The mythical origin of women is the sky, from which they descended. Stars are also considered to be female beings. Hence, there are well-defined links between the sky and the female world. An example of this is the relationship established with the moon. In the narrative level Moon is a masculine entity which conducts the mythological conformation of the Toba woman. Rafael Karsten's 1912 ethnography of the Bolivian Toba also suggests that they thought that menstruation was caused or influenced by the moon (Karsten, 1923, p. 26). The myth about sexual relationships between the moon and women who have had their first period can still be heard among the Toba. The moon is still thought of as a masculine entity which is responsible for the mythological conformation of Toba women. In the words of a Toba, "Moon is the first man of every woman." When their first period appears, mothers still say to their young daughters that the "Moon is to blame." Therefore, in this context mothers utter things such as "It is as if the moon had raped my daughter." As we have already said, according to Toba oral tradition, the moon is responsible for the mythical formation of femininity. Thus, the moon plays the role of the primordial hero "the fox," who let the primeval men in mythical times have sexual intercourse with women who had just descended from their celestial abode. Indeed, as the moon had his first sexual intercourse with the girls and thus helped them get married, the fox had his first sexual intercourse with the celestial women and helped them have their teeth removed from the vaginas and thus become the wives of men. Likewise, the lunar imaginary is used to measure diverse temporal cycles. The Toba explanation about the moon refers to a group of organic ideas which evoke youth, maturity, and death of a living agent (Gómez, 2014b).

Among the Toba of Western Formosa, political leadership is associated with the asterism known as *Dapi'chi*, which is represented by the Pleiades. This asterism controls cold in general. Its appearance also announces the arrival of a new bountiful period starting around December, when the bush abounds in algarroba, and they say that the asterism seems to "vanish" from the sky. According to the evidence gathered, *Dapi'chi* is "a very important man" wearing a red crown that can only be noticed when he first becomes visible, that is, when coming up in the east before dawn, in winter, during his heliacal rising. Just like the Toba leader, *Dapi'chi* is the "leader" because he knows all those under his control: the other stars. *Dapi'chi* is also reinterpreted concurrently with the changes in the blurred political leadership figures among the western Toba Indians (Gómez, 2014a; 2011). On the other hand, this asterism has been critical in accounting for the beginning of a new annual cycle.

Mocoví

The Moqoit or Mocoví belong to the Guaycurú linguistic group. They inhabit the southern area of the Chaco region, in the Argentinean provinces of Chaco and Santa Fe. We will underline two main components of their rich astronomy that are also present in other Chaco groups.

The Milky Way and the *Nayic* as a Conceptual Structure

For the Moqoit, the Milky Way holds many articulated meanings, which are highlighted according to the circumstances or the narrator. A common element throughout these meanings, however, is the structuring role that is played by the Milky Way in Moqoit cosmology (Giménez, López, & Granada, 2002).

Star brightness is related for the Moqoit people to the notion of the brightness of powerful beings. In this sense, the Milky Way and its myriad of stars make up a space seen as

extremely powerful. The different positions of the Milky Way are used for finding the way in woodland at night and as a temporal marker. Beyond these, the Milky Way is seen by Moqoit as a path, a tree, and simultaneously a whirlwind that gives structure and maintains the communication between the different levels of the cosmos. But it is not simply a naive picture: tree, whirlwind, and path act as true models to think about key aspects of the fundamental dynamics and structure of reality as the Moqoit people experience it.

The Moqoit word *nayic* means “path,” and it is related to the idea of going deep into nonhuman space. One such space is the forest, along which a sequence of markers unfolds, each one commemorating a pact with the ruling powers of the world. The notion of “path” is a general Moqoit conception to organize reality: a tale, the life of a human being, the community memory, and the universe itself. The Milky Way is seen as the path followed by the mythic Rhea, the Mañic, as it flees to the sky haunted by the ancestors of the Moqoit. Stories about these events make up a kind of serial narrative linked to the history of the “hunting of Mañic” and are “strung” by means of the Milky Way. In this sense, the representation of the Milky Way as a “path” structures the Mocoví’s oral narrative about stars.

But this path in the sky is also seen as the road of the celestial powerful beings that descends to the Earth and the way in which the *pi’xonaq* or shamans obtain power. The *pi’xonaq*, the specialists of the sacred, have a capacity to see this structure of the universe. Their healing capacity is based on their capacity to travel around the world and build alliances with the entities governing it.

Iron Meteorites, Power, and Colonialism

Given the sediment composition of the Chaco plains, it is very rare to find rocky or metallic objects. The area inhabited by several Moqoit communities is dotted with pieces of this kind related to the sky – iron meteorite fragments making up the strewn field of Campo del Cielo

(Giménez Benítez, López, & Granada, 2004). These pieces are seen as manifestations of the celestial presence on Earth. It is believed that, after falling from the sky and getting buried in the ground, meteorites start to come up to the surface and appear to those people they were designed for, bringing them luck, wealth, and health. The contact between humans and meteorites may cause rainfall, and only shamans are capable of manipulating them with no risk. To the Moqoit, the wealth-generating capacity of meteorite fragments is a manifestation of the power they confer as agents of the “powerful” of the sky.

In this context, the Moqoit believe that the inequality, violence, and exploitation they suffer from the non-aboriginal society are ultimately due to the way in which the latter has monopolized access to the cosmic sources of power. For these reasons, through texts (Martínez, 2006) and public actions, Juan Carlos Martínez and other young Moqoit leaders have demonstrated the connection that the Moqoit see between their notions about the cosmos and their land and cultural claims (López, 2011). In doing so they have emphasized the importance of the relationships between humans and powerful nonhuman beings in shaping Moqoit notions of territory and way of life. They used the Campo del Cielo crater field as a symbol of those relationships. The successful Moqoit resistance to the transportation of the largest meteorite found to Germany for the dOCUMENTA13 art exhibition should be understood in this context (López, 2014c).

Conclusions

The notions that the Chaco aboriginal groups have about the sky are not a whimsical set of quaint and naive fantastic stories. On the contrary, they are part of complex considerations about the world and the humans which involve the use of sophisticated metaphors and elaborate ideas of such notions as identity, personhood, body, causality, and power. Thus, structures are used both to organize the sky around the Milky Way and to shape the account of a person’s life.

Just like the ideas of any human group about the world, these aboriginal conceptions of the sky are not static but change over time. Furthermore, they are related to the life of the societies that generate them, albeit not necessarily being their reflection. In this sense, the intense relations among the various groups in the region, even if belonging to different linguistic groups, are reflected in the multiple interactions between their astronomies. On the other hand and regarding the groups in question, the sky is strongly tied to abundance and power on Earth, so that all considerations about the sky are regarded as major political issues. As these societies are not hierarchical and many social actors vie for leadership, we are faced with a variety of competing versions of the sky and its inhabitants and of how humans can relate to them.

In the groups analyzed, the process of developing ideas about the sky and the competing interpretations thereof are in full force and are not merely a curious thing of the past. Their views of the celestial sphere play a major role in the current struggle for their cultural, territorial, and health-care rights.

Astronomy in the Indo-Malay Archipelago

Gene Ammarell
Athens, OH, USA

All societies have their own systems of knowledge through which they seek to understand the natural environment and their relationship to it. Thus we may be better able to understand a society by going beyond the categories of Western science and begin to consider the interrelationship of a society with its environment from the viewpoint of the members of that society. It is this attempt to understand how members of a society, themselves, conceive of their

environment that has come to be known as ethnoecology (Casiño, 1967). Ethnoastronomy, the subject of this article, may be seen as a branch of ethnoecology wherein the interrelationship of human populations with their celestial environment is the focus of interest.

The modern nation states of Indonesia and Malaysia have a combined population of approximately 260 million and encompass the homelands of well over 500 distinct ethno-linguistic groups whose cultures and languages form part of a common Austronesian heritage, a heritage they share with the majority of the peoples of the Philippines, Polynesia, and Micronesia, among others (In addition, there are at least 100 Papuan languages spoken in the Indonesian province of West Papua on the western half of the island of New Guinea.). Inhabiting mountainsides, river valleys, and coastal plains and faced with a somewhat unpredictable tropical monsoon climate, the peoples of Island Southeast Asia have developed diverse systems of agriculture that include both inundated rice farming and the shifting cultivation of rice and other food crops. Spread across an archipelago of over 17,000 islands (at least 6,000 inhabited), they have also developed sophisticated systems of navigation. These indigenous agricultural and navigational practices have been informed by an astronomical tradition that is, at once, unique to this cultural area and richly diverse in its local variation. This article describes several of the many techniques of astronomical observation that are known to have been employed by the peoples of Indonesia and Malaysia to help regulate their agricultural cycles and navigate their ships.

The Celestial Landscape

The passage of time is mirrored in all of nature: in the light and warmth of day and the dark and coolness of night, in the flowering of plants, in the mating and migratory behavior of animals, in the changes in weather, in the ebb and flood of the tides, and in the recurring cycles within cycles of the sun, moon, planets, and stars as they transit the celestial sphere. Of these cycles, perhaps the

most obvious is the diurnal rising and setting of the sun, moon, planets, and stars, as well as the synodic or cyclic changes in the phase of the moon and in the time of day that it rises and sets. More subtle than these might be the annual changes in the sun and stars: the north-south shift in the path of the sun across the sky (including its rising and setting points and its relative distance above the horizon at noon) and the appearance, disappearance, and reappearance of familiar patterns of stars at various times of night. To the trained eye, nature is replete with signs of diurnal and seasonal change. As an integral part of the natural landscape, these recurring celestial phenomena have long provided farmers and sailors worldwide with dependable markers against which operations, agricultural as well as navigational, can be timed.

Likewise, orientation in space and the art of wayfinding have often relied upon knowledge of these same celestial phenomena, the English term “orient,” itself, having been derived from the Latin for “rise” and later associated with the East as the direction in which the sun appears at dawn. Although the times that individual stars rise and set shift gradually throughout the year, as viewed from a given latitude, the azimuths at which a star rises and sets varies only slightly over a lifetime, thereby providing a reliable “star compass” by which to determine direction. So, too, the sun, moon, and planets rise and set generally [▶ east and west](#), depending upon their individual cycles, affording additional guides by that people are able to orient themselves on the land as well as on the sea.

Agricultural Time Keeping

Many traditional, sedentary desert and plains cultures have used the shift in the rising and/or setting points of the sun along the horizon to both mark important dates and seasons and to commemorate the passage of years. Desert and plains environments are conducive to the development and use of these horizon-based solar calendars: a permanent location from which to make sightings, a series of permanent distant horizon

markers, either natural or manufactured, and a clear view are all that is needed for such a calendar. England's Stonehenge and Wyoming's Big Horn Medicine Wheel provide striking examples. Such conditions, however, are not common across much insular Southeast Asia. Here the landscape may consist of anything from a nearby or distant mountain to, more often, nearby trees; the horizon is, therefore, a rather undependable device against which to sight and measure the rising and setting positions of the sun. But in cultivated areas of the region, even from swidens located deep within the rainforest, one can usually find a field or home site from which much of the sky is visible.

There are several types of observations of annually recurring celestial phenomena that can be made where permanent, distant horizon markers are not commonly available. These include cyclic changes in the phases of the moon, the annual changes in the apparitions of familiar groups of stars, and the annual changes in the altitude of the sun at noon. Here I present variations of these types of observations that we know have been practiced among traditional farmers of Indonesia. For the sake of clarity, they are grouped using Western astronomical categories as follows: solar gnomons, apparitions of stars at dawn and dusk, and lunar-solar and sidereal-lunar observations.

Solar Gnomons. Most often seen on sundials in western cultures, a solar gnomon is simply a vertical pole or other similar device that is used to cast a shadow. The altitude of the sun above the horizon varies not only through the day, however, but through the year as well. By measuring the relative length of this shadow each day at local solar noon, one can observe and more or less accurately measure the changing altitude of the sun above the horizon (or, reciprocally, from the zenith) through the year and, thereby, determine the approximate date.

Two distinct types of solar gnomons have been reported in the region. Both measure the altitude of the sun at local solar noon to determine the date. One type has been attributed to various groups of the Kenyah of the Apo Kayan of Kalimantan and may still be in use (Fig. 1).

Astronomy in the Indo-Malay Archipelago,
Fig. 1 Kenyah *tukar do* or solar gnomon (From Hose & McDougall, 1912)

Astronomy in the Indo-Malay Archipelago,
Fig. 2 Kenyah *aso do* or base of solar gnomon (Adapted from Hose, 1905)

It consists of a precisely measured (=span of maker's outstretched arms + span from tip of thumb to tip of first finger), permanently secured, plumbed, and decorated vertical hardwood pole (*tukar do*) and a neatly worked, flat measuring stick (*aso do*), marked with two sets of notches (Fig. 2). The first set corresponds to specific parts of the maker's arm and ornaments worn upon it, measured by laying the stick along the radial side of the arm, the butt end against the inside of the armpit.

Astronomy in the Indo-Malay Archipelago, Fig. 3 The base of the *bencet* or solar gnomon showing the grid used to measure the length of the sun's shadow (Maass, 1924)

To mark the date, the measuring stick is placed at the base of the vertical pole, butt end against the pole and extending southward. This is done at the time of day that the shadows are shortest, local solar noon. On the day that the pole's noon-time shadow is longest (the June solstice), a notch is carved on the other edge of the stick to mark the extent of the shadow made by the pole. This observation indicates that the agricultural season is at hand. From then on, the extent of the noon-day shadow is recorded every 3 days as a record-keeping device. Dates, both favorable and unfavorable, for various operations in rice cultivation, such as clearing, burning, and planting, are determined by the length of the shadow relative to the marks on the stick that correspond to parts of the arm and to the marks made every 3 days (Hose, 1905; Hose & McDougall, 1912).

On Java a highly accurate gnomon, called a *bencet*, was in use from about AD 1600 until 1855 (Figs. 3 and 4) (Maass, 1924; see also Ammarell, 1996, 1998; Aveni, 1981; van den Bosch, 1980). A smaller, more portable device than that employed by the Kayan and Kenyah, the *bencet* divides the year into 12 unequal periods,

Astronomy in the Indo-Malay Archipelago, Fig. 4 Javanese *bencet* and the annual motion of the sun (Adapted from Aveni, 1981)

called *mangsa*, two of which begin on the days of the zenith sun, when the sun casts no shadow at local solar noon, and another two of which begin on the two solstices, when the sun casts its longest mid-day shadows.

At the latitude of Central Java, 7° south, a unique condition exists which is reflected in the *bencet*. As the illustration shows, when, on the June solstice, the sun stands on the meridian (that is, at local solar noon) and to the north of the zenith, the shadow length, measured to the south of the base of the vertical pole, is precisely double the length of the shadow, measured to the north, which is cast when the sun, on the December solstice, stands on the meridian (at noon) south of the zenith. By simply halving the shorter segment and quartering the longer, the Javanese produced a calendar with 12 divisions, divisions that are spatially equal but which range in duration from 23 to 43 days. The 12 *mangsa* with their starting dates and numbers of days are shown on Table 1.

Astronomy in the Indo-Malay Archipelago,
Table 1 The Pranatamangsa calendar (Adapted from
 van den Bosch, p. 250)

Ordinal number	Name(s) of <i>mangsa</i>	Duration (days)	First day(s) civil calendar
<i>Ka - 1</i>	<i>Kasa</i>	41	22 (21) June
<i>Ka - 2</i>	<i>Karo, Kalih</i>	23	2 (1) August
<i>Ka - 3</i>	<i>Katelu, Katiga</i>	24	25 (24) August
<i>Ka - 4</i>	<i>Kapat, Kasakawan</i>	25	18 (17) September
<i>Ka - 5</i>	<i>Kalima, Gangsal</i>	27	13 (12) October
<i>Ka - 6</i>	<i>Kanem</i>	43	9 (8) November
<i>Ka - 7</i>	<i>Kapitu</i>	43	22 (21) December
<i>Ka - 8</i>	<i>Kawolu</i>	26 (27)	3 (2) February
<i>Ka - 9</i>	<i>Kasanga</i>	25	1 March (ult. February)
<i>Ka - 10</i>	<i>Kasepuluh, Kasadasa</i>	24	26 (25) March
<i>Ka - 11</i>	<i>Desta</i>	23	19 (18) April
<i>Ka - 12</i>	<i>Sada</i>	41	12 (11) May

Apparitions of Stars at Dawn and Dusk. The second category of observational techniques regularly employed by traditional farmers of the region include all of those which involve apparitions of commonly recognized stars or groups of stars (which are herein referred to as “asterisms”) at last gleam at dawn or first gleam at dusk (I use the term “asterism” to refer to a commonly recognized patterned grouping of stars. While these groupings are often referred to generically as “constellations,” I reserve the latter term to refer to the 88 bounded regions of the sky generally accepted by international scientific astronomers, these regions often named for asterisms found within their borders. Note, however, in Western starlore, there may be two or more asterisms within one constellation (e.g., the “Big Dipper” and the “Great Bear” in Ursa Majoris).). Because of the earth’s orbital motion about the sun, it can be observed that each star rises and sets approximately 4 min earlier each night. Similarly, each star appears to have moved about 1° west, when viewed at the same time, each night. As a result, around the time of its conjunction with the sun, any given star becomes lost in the sun’s glare and is, therefore, not visible for approximately

1 month each year. It also means that the altitudes of stars above the horizon vary as a function of both the time of night and the day of the year, such that a certain star or group of stars, when observed at the same time each night (in this case near dusk or dawn) will appear at a given altitude above the eastern or western horizon on one and only one night of the year. Hence the use of any technique or device to measure the altitude of a star or group of stars as it appears at first or last gleam can provide the observer with the approximate date.

I use the term “acronical” to refer to any stellar apparition that occurs at first gleam while “cosmical” is used to describe stars at last gleam. A subset of these, “heliacal” (Greek *helios*: “sun”) apparitions of stars are those that occur just prior to and shortly after conjunction with the sun. The heliacal setting of a star or group of stars occurs on the date that the star or stars are last observed before conjunction, just above the western horizon at dusk. Likewise, the heliacal rising of a star or group of stars occurs on the date that the star or stars are first observed above the eastern horizon at dawn after several weeks’ absence.

Just about 3 months after its heliacal rising, the star, now about 90° west of the sun, appears on the meridian at first gleam, an event that may be termed a “cosmical culmination” of the star. Two months later, the star is nearing opposition with the sun and undergoes an “acronical rising” in the east at first gleam. In less than 1 month, after opposition, the “cosmical setting” of the star is seen in the western sky. After 2 more months the star may be seen on the meridian at first gleam, accomplishing its “acronical culmination.” Finally, about 3 months later, the star undergoes “heliacal setting” as the sun once again outshines it.

I would like to emphasize that these categories are taken from what is often referred to as the “exact science” of Western mathematical astronomy and are used here as a way of organizing and presenting this material to the Western scholar. The reader is cautioned that the actual observations made by indigenous farmers may not always be as precise as their assigned astronomical categories might imply. The demand for such

Astronomy in the Indo-Malay Archipelago,

Fig. 5 Bamboo device used by Kenyah-Kayan to measure the altitude of a star (Adapted from Hose & McDougall, 1912)

precision varies greatly between and within cultures and with local environmental conditions. Here it would not be unusual to find a local farmer, for example, first noting the heliacal rising of the star cluster known in the West as the Pleiades at dawn several days or more after its mathematically calculated reappearance. Note that for convenience, I refer in this article to stars and asterisms by their accepted international scientific names. Where I know the name of a star or asterism in the indigenous language, I will note it as well.

The apparitions of stars at first and last gleam have been systematically observed by traditional cultures worldwide. From island Southeast Asia there are references in the literature, too numerous to describe in detail here, to the calendrical use at both dusk and dawn of the stars known internationally as the Pleiades, Orion and, to a lesser extent, Antares, Scorpius, and Crux (for more Indo-Malay examples, see Ammarell, 1988, 1996; for examples from the Philippines, see Ambrosia, 1996). Culminations at both first

and last gleam of the Pleiades, Orion, and Sirius are noted in the literature. Interestingly, the observation for calendrical purposes of such culminations seems to be unique to peoples of this culture area.

A small Dayak group related to the Kenyah-Kayan complex mentioned earlier practiced the first example in this category. Like their neighbors, they were ►swidden rice farmers. But unlike their neighbors who tracked the sun, they depended upon the stars to fix the date of planting. To do so, they nightly poured water into the end of a vertical piece of ►bamboo in which a line had been inscribed at a certain distance from the open end (Fig. 5a). The bamboo pole was then tilted until it pointed toward a certain star (unrecorded) at a certain time of night (also unrecorded), causing some of the water to pour out (Fig. 5b). It was then made vertical again and the level of the remaining water noted (Fig. 5c). When the level coincided with the mark, it was time to plant (Hose & McDougall, 1912).

Astronomy in the Indo-Malay Archipelago,

Fig. 6 Javanese ritual specialist holding rice in open palm at dusk, pointing toward the rising *bintang weluku* “plough stars” (Orionis)

A

Near Yogyakarta, Central Java, a ritual practitioner was observed raising his hand toward the East in the direction of *bintang weluku* “plough stars” (Orionis) each day at dusk, rice seed in his open palm (Fig. 6). On the night it reached the altitude such that kernels of rice rolled off his palm (angle of repose), it was time to sow seed in the nursery (van den Bosch, 1980). Using a planetarium star projector, the author has determined the date of this event to be about 4 January (Ammarell, 1996).

Lunar Calendars. Lunar calendars comprise the third category. These calendars are based upon the 29.5-day synodic period, usually measured from new moon to new moon and often subdivided by phase. Because there is not an even number of lunar months in a solar year and because agricultural cycles are, after all, tied to the solar year, simple lunar calendars alone are of little use in farming. But when they are somehow pegged to the solar year by reference to the apparent annual changes in the positions of the sun or stars or to other phenomena in nature that regularly recur on an annual basis, a lunar calendar can be of use to the farmer.

Indigenous lunar calendars fall into two general categories: lunar-solar and sidereal-lunar. Examples of the lunar-solar calendar include the Balinese ceremonial calendar, still in use, and the old Javanese *Saka* calendar, used from the eighth

to the sixteenth centuries. Both are apparently of a common Hindu origin and are primarily lunar; both employ complex mathematical techniques to provide the intercalary days that periodically synchronize the lunar with the solar year (Covarrubias, 1937; van den Bosch, 1980).

A second type of lunar calendar, best described as sidereal-lunar, uses the apparitions at dusk and dawn of stars and asterisms as well as the appearance of other signs in nature (such as winds, birds and flowers) to determine which month is current. In these cases, it is only important to know which month it is for a few months each year (that is, during the agricultural season), thereby obviating the need for codified schemes for realigning the lunar with the solar/stellar year. Such “short” lunar calendars are found spread throughout the region (see Ammarell, 1988). The Iban calendar provides a good example.

The Iban Calendar

Freeman (1970) describes the Iban as a riverine people practicing shifting agriculture in the vicinity of their longhouses, situated in low hills of Sarawak and West Kalimantan. The stars have played a central role in Iban mythology and agricultural practices. Several Iban stories tell how their knowledge of the stars was handed down to

them by their deities and according to one village headman, “If there were no stars we Iban would be lost, not knowing when to plant; we live by the stars” (Freeman, 1970, p. 171). The Iban lunar calendar was annually adjusted to the cosmical apparitions of two groups of stars: the Pleiades and the three stars of Orion’s belt.

The first observation was probably the most difficult. It was the reappearance of the Pleiades on the eastern horizon just before dawn after 2 month’s absence from the night sky. This heliacal sighting, around 5 June of the civil calendar, informed the observer that the month, taken from new moon to new moon, that is current is, by convention, the fifth lunar month. It is during this month that two members of the longhouse went into the forest to seek favorable omens so that the land selected would yield a good crop. This may have taken from 2 days to a month, but once the omens appeared, they returned to the longhouse and work clearing the forest began. If it took so long for the omens to appear that Orion’s belt rose before daybreak (heliacal rising around 25 June), the people had to “make every effort to regain lost time or the crop will be poor” (Freeman, 1970, p. 171). This reappearance of Orion at dawn occurred during the next or sixth lunar month, the time to begin clearing the land.

The remaining observations of the stars were more easily accomplished. They are all cosmical culminations, occurring “overhead” at last gleam, and could be seen to be approaching for several weeks. When the Pleiades underwent its cosmical culmination (3 September) and the stars of Orion’s belt were about to do so (26–30 September), it was the eighth month and time to burn and plant. For good yields the burn should have occurred between the time that the two asterisms culminated at first gleam, usually when the two were in balance or equidistant from the meridian (16 September). Rice seed sown after the star Sirius had completed its cosmical culmination (October 15) would not have matured properly. It was okay for planting to carry into the tenth lunar month (October/November), but it had to be completed before the moon was full or the crop would fail. At this point the lunar calendar ended: only months five

through ten were numbered and fixed while the remaining months varied according to how quickly the crop matured (e.g., *bulan mantun*, the “weeding month”). The lunar months from November to April were simply not numbered; it was difficult to see the stars during the rainy season and unimportant in any case.

Celestial Navigation

As we have just seen, the rice farmers of Indonesia have long noted correlations between celestial and terrestrial cycles and incorporated periodic changes in the sky into their agricultural calendars. Meanwhile, neighboring seafaring societies have used many of these same phenomena to orient themselves in both space and time for the purpose of navigation. Of these societies, the Bugis of South Sulawesi are perhaps the best known. Maintaining a tradition of seafaring and trade that spans at least four centuries, the Bugis are reputed to have established and periodically dominated strategic trade routes across Southeast Asia, stretching northeast from North Sumatra to Cambodia, north to Sulu and Ternate, and east to Aru and Timor. Their maritime prowess notwithstanding, Bugis systems of navigational knowledge and practice have only recently come under study (Ammarell, 1995, 1999).

Bugis navigators still employ a system of dead reckoning that depends upon the knowledge of a variety of features of the natural environment to negotiate the seas in their tall ships. Although these features include land forms, sea marks, currents, tides, wave patterns and shapes, and the habits of birds and fish, navigators rely most heavily upon the prevailing wind directions, guide stars, waves, swells, and, increasingly, the magnetic compass.

Winds and Directions. The major wind patterns across island Southeast Asia are governed by the monsoons. In the Java and Flores Seas, from approximately May through October, winds from the east and southeast bring generally fair weather and steady breezes; from November through April, the west monsoon brings first calm air, then rain and squalls to the region.

For the Bugis as well as a number of other regional ethnic groups whose languages share a common Austronesian heritage, these winds are of such fundamental importance that their names are synonymous with the local prevailing wind directions. Thus for the Bugis, both the monsoons and their prevailing directions in the vicinity of their homeland of South Sulawesi are: *bare* ‘west’ and *timo* ‘east.’ (For an exceptionally thorough historical and comparative discussion of concepts of orientation is several South Sulawesi languages, see Liebner (2005).)

For the Bugis of the small coral islet of Balobaloang, located midway between Makassar on Sulawesi and Bima on Sumbawa, trade routes are generally north and south across the Flores Sea. In principle, this allows them to take advantage of both easterly and westerly winds by reaching in either direction, although storms and heavy seas usually confined them, in the past, to port during the west monsoon. Formerly voyages were undertaken during the west monsoon only if the captain was hard pressed financially. Now, with motorization and larger ships, the voyaging season has been increasingly extended such that confinement to port is restricted to brief periods of severe weather, usually lasting no more than a week or two at a time.

Stars and Asterisms. Bugis navigators have long relied upon the stars and star patterns to set and maintain course. Although most sailors seem to know a few star patterns and their use, the navigators have been found to know many more. These star patterns, or asterisms, are known to rise, stand, and/or set above certain islands or ports when viewed from others and thereby pinpoint the direction of one’s destination forming a “star compass.” For example, in late July and early August *bintoéng balué* “Alpha&Beta Centauri” (Asterism A, Fig. 7) is known to make its nightly appearance at dusk in the direction of Bima as viewed from Balobaloang, that is, to the south.

As the night passes and a given asterism is no longer positioned over the point of destination, the navigator’s thorough Gestalt-like familiarity with the sky allows him mentally to adjust to the new conditions: he can derive through

visualization the points on the horizon at which the stars rise or set relative to wherever they currently appear. When a certain asterism simply is not visible, other associated but unnamed stars may be used to remind the navigator where the original asterism set or is about to rise or they may be used instead of the missing asterism. This, by the way, appears to be analogous to the “star path, the succession of rising or setting guiding stars down which one steers” described by Lewis for several cultures in Polynesia and Micronesia (1972, pp. 46–47). The stars identified by Bugis navigators are listed in Table 2 and illustrated in Figs. 7 and 8; those which are most relied upon will now be described.

Perhaps the most frequently used asterism among the Bugis of Balobaloang is that *bintoéng balué*, mentioned above. These two bright stars are used to locate Balobaloang from Makassar and Bima from Makassar or Balobaloang. With regard to their rise/set points, navigators observe that they appear “in the south” at dusk during toward the middle of the east monsoon, the peak period for sailing; they further note that they rise “southeast” and set “southwest.” Their brightness makes them visible even through clouds. The name *balué* is derived from *balu* that means “widow from death of the betrothed before marriage” with the affix *é* forming the definite article. Hence: “the one widowed before marriage.” No graphical figure is attributed to this asterism.

Just to the west of “Alpha&Beta Centauri” is *bintoéng bola képpang* (Crux), visualized as an “incomplete house of which one post is shorter than the other and, therefore, appears to be limping” (B in Fig. 7). Crux is used in conjunction with Alpha and Beta Centauri to navigate along southerly routes; like Alpha and Beta Centauri, it is known to set “southwest.” Interestingly, it was emphasized that Crux is also used to help in predicting the weather. This asterism is located in the Milky Way that is known to the Bugis as *bintoéng nagaé* “the dragon,” whose head is in the south and whose tail wraps all around the sky. As such, a bright haze of starlight surrounds Crux. On the eastern side of the house, however, there is a small dark patch totally devoid of light which is seen as a *bembé* ‘goat’

Astronomy in the Indo-Malay Archipelago,

Fig. 7 Bugis navigational stars: southern sky

Astronomy in the Indo-Malay Archipelago, Table 2 Bugis stars and asterisms familiar to navigators

Asterism	Bugis name ^a	English gloss	International designation
A	<i>bintoéng balué</i>	Widow-before-marriage	Alpha and Beta Centauri
B	<i>bintoéng bola képpang</i>	Incomplete house	Alpha-Delta, Mu Crucis
B.1	<i>bembé</i>	Goat	Coal Sack Nebula in Crux
C	<i>bintoéng balé mangngiweng</i>	Shark	Scorpius (south)
D	<i>bintoéng lambarué</i>	Ray fish, skate	Scorpius (north)
D.1	(Identified w/o name)	Lost Pleiad	Alpha Scorpii (Antares)
E	<i>bintoéng kappala`é</i>	Ship	Alpha-Eta Ursa Majoris
F	<i>bintoéng kappala`é</i>	Ship	Alpha-Eta Ursa Majoris; Beta, Gamma Ursa Minoris
G	<i>bintoéng balu Mandara`</i>	Mandar widow	Alpha, Beta Ursa Majoris
H	<i>bintoéng timo` or bintoéng timoro` (Mak)^b</i>	Eastern star	Alpha Aquilae (Altair)
J	<i>pajjékoé (Mak.)^b or bintoéng rakkalaé</i>	Plough stars	Alpha-Eta Orionis
J.1	<i>tanra tellué</i>	Sign of three	Delta, Epsilon, Zeta Orionis
K	<i>worong-poronggé bintoéng pitu</i>	Cluster seven stars	M45 in Taurus (Pleiades)
M	<i>tanra Bajoé</i>	Sign of the Bajau	Large and small magellanic clouds
□	<i>wari-warié</i>	(No gloss)	Venus: morning
□	<i>bintoéng bawi</i>	Pig star	Venus: evening
□	<i>bintoéng nagaé</i>	Dragon stars	Milky way

^aThe Bugis term for “star(s)” is *bintoéng*; the suffix *é* may be translated as the definite article “the” in English

^bAlthough *timoro`* and *pajjékoé* are Makassar terms, they are more commonly used than the Bugis terms on Balobaloang

(B.1 in Fig. 7). Between the squall clouds of the rainy season the goat in the sky may be seen standing, as goats are wont to do, outside the house trying to get in out of the rain. There are

nights, however, when the goat is gone from the protection of the house. Hidden by haze, the missing goat portends a period of calm air and little rain.

Astronomy in the Indo-Malay Archipelago,

Fig. 8 Bugis navigational stars: northern sky

A

In the northern sky the asterism that figures most prominently in Bugis navigation is known as *bintoé ng kappala'é*, “the ship stars” in the international constellation of Ursa Majoris (two versions, E and F, in Fig. 8). The “ship” is used when traveling north and is known to rise “northeast” and sets “northwest” over Kalimantan from the port city of Makassar and from Balobaloang. Associations of this group of stars with the hull of a boat or ship appear to be common throughout the region.

The two stars of *balu Mandara* “widow of the Mandar” (G in Fig. 8) adjoin the “ship” and are likewise used to navigate northward. These two stars, Alpha and Beta Ursa Majoris, remind the Bugis of Alpha and Beta Centauri (thus the name *balu*), while “Mandar” recalls their northern seafaring neighbors.

Several asterisms and a planet are used for sailing ► east and west. They include: *timoro* (Makassar) or *bintoéng timor* (Bugis) “eastern star” (Altair; H in Fig. 8); *pajjékoé* (Makassar) or *bintoéng rakkalaé* (Bugis) “the plough stars” (Alpha-Eta Orionis; J in Figs. 7 and 8); *tanra tellué* “the sign of three” (Delta, Epsilon, Zeta Orionis; J.1 in Figs. 7 and 8); *wari-warié* [no gloss] or *bintoéng élé* “morning star” (Venus in predawn sky); and *bintoéng bawi* “pig star” (Venus in evening sky), so named since it is believed that wild pigs will enter and destroy a garden or orchard when this object shines

brightly in the west. Both the “pig star” and the “plough,” by the way, speak to an agrarian lifestyle not practiced by Bugis seafarers but culturally shared with their kin who farm the lands of South Sulawesi as well as other islands of the archipelago. See Pelras (1987) for the astronomical knowledge of Bugis rice farmers.

Although the stars are useful guides, they are not always visible. Because it is possible to see landfall during the day, navigators appear to plan their voyages so as to maximize its usage. On a voyage from Balobaloang to Bima, the captain scheduled the departure for mid-afternoon allowing him to back-sight on Balobaloang and other islands of the atoll and observed the sun as it set in the west until dusk when Alpha and Beta Centauri appeared in the sky. There was, in fact, a period of about 30 min where both the receding island and the stars could be seen, providing a good opportunity to maintain course as attention was shifted from land forms to the stars.

Except during the height of the west monsoon, it is uncommon to experience extended periods of totally overcast skies. Should, however, the primary guiding asterism may be concealed by clouds, the navigator depends upon his knowledge of other asterisms or unnamed stars to fix his direction. If it is very cloudy, day or night, the navigator turns to wave directions and the magnetic compass to maintain course.

Although the more experienced navigators say that they could do without it and rely on wind, waves, and stars, the magnetic compass plays a central role in contemporary Bugis navigation and their presence should be of no surprise. Magnetic compasses, Liebner (2005) points out, have been used aboard the larger inter-island ships since the eighteenth century. On frequently sailed routes the helmsman knows from experience or from the navigator's instructions the proper compass bearing which will guide the boat toward its objective. At night under mostly clear skies, the helmsman points the ship's bow toward a succession of guide stars whose own azimuths change as the night passes. To compensate for this change, he checks the compass about once per hour, sometimes after several minutes of calling to a sleepy crew member for a flashlight or match by which to see it. On cloudy nights, when few or no stars are to be seen, the helmsman's job is much harder. Complicated by an often-unsteady helm, the helmsman is forced to check the compass every minute or so with a flashlight whose batteries are soon run down through constant use. By day the compass is generally observed more often regardless of the weather, although the sun, when low in the sky, is used as a reference.

Courses are committed to memory in terms of destinations and their required compass headings under various winds. That is, certain points of the compass are associated with certain destinations from various ports. For example, it is known that to sail from Balobaloang to Bima during the east monsoon, one must head due south, while during the west monsoon one heads south-southwest to southwest, depending on the strength of the wind and current. Likewise, to reach Makassar from the island during the east monsoon one travels somewhat east of north, while during the west monsoon a heading to the north-northwest is preferred. This difference, as navigators are quick to point out, takes into account drift from wind and currents, while true directions are also known. Practiced navigators have many of these bearings committed to memory and will refer to the experience of others as well as to charts and maps when they wish to travel to new or infrequent destinations.

On the author's initial voyage aboard a Bugis ship, the route traveled was well known to the seafarers of Balobaloang: Makassar to Bima via the island, a distance of about 212 nautical miles. Over the course of 4 days and 5 nights at sea without an auxiliary engine – and on later voyages after an engine had been installed – only occasionally were the helmsman or captain seen referring to the compass, and rarely at night or when in sight of land. When asked about this, both agreed that the compass could be used through the night, but to do so one would have to light the flashlight “so why not just use the stars?” Even if the compass were thrown overboard, we were assured the navigator could find his way.

Summary and Conclusion

This article has presented several examples of indigenous Indonesian calendrical and navigational systems and describes the celestial observations upon which they are based. It has also attempted to provide categories, drawn from international scientific astronomy, into which these observations may be placed.

With regard to the study of indigenous astronomical systems worldwide, there appear in regional agricultural calendars two types of celestial observations that may be unique to this cultural region. They are (1) observations of “cosmical” and “acronical” culminations – meridian transits at last and first gleam – of groups of stars and (2) observations of the lunar month for a limited number of months each year, creating discontinuous sidereal-lunar calendars. The use of stars by the Bugis navigators of South Sulawesi likewise appears represent a system that, along with its transformations used by Oceanic mariners, appears to be unique to the Austronesian world.

Implicit in the discussion of agricultural calendrical and navigation systems is the understanding that celestial observations do not stand alone. That is, many other environmental markers – changes in wind and weather and the appearances of flora and fauna also inform agricultural and

navigational decision-making. It is suggested that by noting more carefully these and other signs in nature to which members of non-Western societies attend, we may gain a deeper appreciation of the true richness of human knowledge across cultures.

Astronomy in the Islamic World

David A. King

Frankfurt University, Frankfurt am Main, Germany

From the ninth to the fifteenth century, Muslim scholars excelled in every branch of scientific knowledge; their contributions in astronomy and mathematics are particularly impressive. Even though there are an estimated 10,000 Islamic astronomical manuscripts and close to 1,000 Islamic astronomical instruments preserved in libraries and museums, and even if all of them were properly catalogued and indexed, the picture that we could reconstruct of Islamic astronomy, especially for the eighth, ninth, and tenth centuries, would still be quite deficient. Most of the available manuscripts and instruments date from the later period of Islamic astronomy, i.e., from the fifteenth to the nineteenth century, and although some of these are based or modeled on earlier works, many of the early works are extant in unique copies and others have been lost almost without trace; i.e., we know only of their titles. The thirteenth century Syrian scientific biographer Ibn al-Qifā relates that the eleventh century Egyptian astronomer Ibn al-Sanbadī heard that the manuscripts in the library in Cairo were being catalogued and so he went to have a look at the works relating to his field. He found 6,500 manuscripts relating to astronomy, mathematics, and philosophy. Not one of these survives amongst the 2,500 scientific manuscripts preserved in Cairo today.

The surviving manuscripts thus constitute but a small fraction of those that were actually copied; nevertheless they preserve a substantial part of the Islamic scientific heritage, certainly enough of it for us to judge its level of sophistication. Only in the past few decades has the scope of the activity and achievements of Muslim scientists become apparent, and the days are long past when they were regarded merely as transmitters of superior ancient knowledge to ignorant but eager Europeans. Islamic astronomy is to be viewed on its own terms. The fact that only a small part of the available material, mainly Greek and Indian material in Arabic garb, was indeed transmitted to Europe is to be viewed as an accident of Islamic history. There is no need to apologize for using the expression “Islamic astronomy.” Within a few decades of the death of the Prophet Muḥammad in the year 632, the Muslims had established a commonwealth stretching from Spain to Central Asia and India. They brought with them their own folk astronomy, which was then mingled with local traditions, and they discovered the mathematical traditions of the Indians, Persians, and Greeks, which they mastered and adapted to their needs. Early Islamic astronomy was thus a pot-pourri of pre-Islamic Arabian starlore and Indian, Persian, and Hellenistic astronomy, but by the tenth century Islamic astronomy had acquired very distinctive characteristics of its own. Sabra (1987) labels this process “appropriation and naturalization.”

Astronomy flourished in Islamic society on two different levels: folk astronomy, devoid of theory and based solely on what one could see in the sky, and mathematical astronomy, involving systematic observations and mathematical calculations and predictions. Folk astronomy was favored by the scholars of the sacred law (*fuqahā*), not least because of various religious obligations that demanded a basic knowledge of the subject; these legal scholars generally had no time (or need) for mathematical astronomy. That discipline was fostered by a select group of scholars, most of whose activities and pronouncements were, except in the case of astrological predictions, of little interest to society at large.

The astronomers also played their part in applying their discipline to certain aspects of Islamic religious practice. It was not Islam that encouraged the development of astronomy but the richness of Islamic society, a highly literate, tolerant, multiracial society with a predominant cultural language, Arabic: but neither did Islam, the religion, stand in the way of scientific progress. The Prophet had said: “Seek knowledge, even as far as China.” To be sure, overzealous orthodox rulers occasionally pursued, killed, or otherwise attacked “scientists” or destroyed or burnt their libraries, but these were exceptions. The scholars of the religious law, who saw themselves as the representatives of Islam, generally ignored the pronouncements of the scientists, even on matters relating to religious practice. Astronomy was the most important of the Islamic sciences, as we can judge by the volume of the associated textual tradition, but a discussion of it in the broader context of the various branches of knowledge, which has been attempted several times elsewhere, is beyond the scope of this essay.

Arab Starlore

The Arabs of the Arabian peninsula before Islam possessed a simple yet developed astronomical folklore of a practical nature. This involved a knowledge of the risings and settings of the stars, associated in particular with the acronychal settings of groups of stars and simultaneous heliacal risings of others, which marked the beginning of periods called *naw*’, plural *anwā*’. These *anwā*’ eventually became associated with the 28 lunar mansions, a concept apparently of Indian origin. A knowledge of the passage of the sun through the 12 signs of the zodiac, associated meteorological and agricultural phenomena, the phases of the moon, as well as simple time-reckoning using shadows by day and the lunar mansions by night, formed the basis of later Islamic folk astronomy.

More than 20 compilations on the pre-Islamic Arabian knowledge of celestial and meteorological phenomena as found in the earliest Arabic

sources of folklore, poetry, and literature are known to have been compiled during the first four centuries of Islam. The best known is that of ► [Ibn Qutayba](#), written in Baghdad about the year 860. Almanacs enumerating agricultural, meteorological, and astronomical events of significance to local farmers were also compiled; several examples of these survive from the medieval Islamic period, one such being for Cordoba in the year 961. The Yemen possessed a particularly rich tradition of folk astronomy, and numerous almanacs were compiled there.

Since the sun, moon, and stars are mentioned in the *Qurʾān*, an extensive literature dealing with what may well be labeled Islamic folk cosmology arose. This was inevitably unrelated to the more “scientific” Islamic tradition based first on Indian sources and then predominantly on Greek ones. Since it is also stated in the *Qurʾān* that man should use these celestial bodies to guide him, the scholars of the religious law occupied themselves with folk astronomy.

Persian and Indian Sources

The earliest astronomical texts in Arabic seem to have been written in Sind and Afghanistan, areas already conquered by the Muslims in the seventh century. Our knowledge of these early works is based entirely on citations from them in later works. They consisted of texts and tables and were labeled ► [zīj](#) after a Persian word meaning “cord” or “thread” and by extension “the warp of a fabric,” which the tables vaguely resemble. The Sasanian *Shahriyārān Zīj* in the version of Yazdigird III was translated from Pahlavi into Arabic as the *Shāh Zīj*, and the astronomers of al-Manṣūr chose an auspicious moment to find his new capital Baghdad using probably an earlier Pahlavi version of this *zīj*. The various horoscopes computed by Māshāʾallāh (Baghdad, ca. 800) in his astrological world history are based on it.

Significant for the subsequent influence of Indian astronomy in the Islamic tradition was the arrival of an embassy sent to the court of the Caliph al-Manṣūr from Sind ca. 772. This

embassy included an Indian well versed in astronomy and bearing a Sanskrit astronomical text apparently entitled the *Māhasiddhānta* and based partly on the *Brāhmasphuṭasiddhānta*. The Caliph ordered al-Fazārī to translate this text into Arabic with the help of the Indian. The resulting *Zīj al-Sindhind al-kabīr* was the basis of a series of *zīj*es by such astronomers as al-Fazārī, ► [Yaʿqūb ibn ṭāriq](#), ► [al-Khwārizmī](#), and others, all prepared in Iraq before the end of the tenth century. The *Sindhind* tradition flourished in Andalusia, mainly through the influence there of the *Zīj* of al-Khwārizmī (see below). As a result, the influence of Indian astronomy is attested from Morocco to England in the late Middle Ages.

Greek Sources

The *Almagest* of Ptolemy (Alexandria, ca. 125) was translated at least five times in the late eighth and ninth centuries. The first was a translation into Syriac and the others were into Arabic, the first two under ► [al-Maʾmūn](#) in the middle of the first half of the ninth century, and the other two (the second being an improvement of the first) towards the end of that century. All of these were still available in the twelfth century, when they were used by Ibn al-ṣalāḥ for his critique of Ptolemy’s star catalogue. The translations gave rise to a series of commentaries on the whole text or parts of it, many of them critical, and one, by Ibn al-Haytham (ca. 1025), actually entitled *al-Shukūk fī Baṭlamīyūs* (Doubts about Ptolemy). The most commonly used version in the later period was the recension of the late ninth century version by the polymath ► [Naṣīr al-Dīn al-Ṭūsī](#) in the mid-thirteenth century. Various other works by Ptolemy, notably the *Planetary Hypotheses* and the *Planisphaerium*, and other Greek works, including the short treatises by Autolycos, Aristarchos, Hypsicles, and Theodosios, and works on the construction known as the analemma for reducing problems in three dimensions to a plane, were also translated into Arabic; most of these too were later edited by al-Ṭūsī. In this way Greek planetary

models, uranometry, and mathematical methods came to the attention of the Muslims. Their redactions of the *Almagest* not only reformulated and paraphrased its contents, but also corrected, completed, criticized, and brought the contents up to date both theoretically and practically.

Theoretical Astronomy

The geometrical structure of the universe conceived by Muslim astronomers of the early Islamic period (ca. 800–1050) is more or less that expounded in Ptolemy's *Almagest*, with the system of eight spheres being regarded essentially as mathematical models. However, in Ptolemy's *Planetary Hypotheses* these models are already taken as representing physical reality; this text also became available in Arabic. Several early Muslim scholars wrote on the sizes and relative distances of the planets, and one who proposed a physical model for the universe was Ibn al-Haytham (fl. Cairo, ca. 1025). In order to separate the two motions of the eighth sphere, the motion of the fixed stars due to the precession of the equinoxes, and the motion of the fixed stars due to the apparent daily rotation, he proposed a ninth sphere to impress the apparent daily rotation on the others.

Of considerable historical interest are various Arabic treatises on the notion of the trepidation of the equinoxes. This theory, developed from Greek sources, found followers who believed that it corresponded better to the observed phenomena than a simple theory of uniform precession. The mathematical models proposed were complex and have only recently been studied properly (notably those of Pseudo-Thābit (date unknown) and ► [Ibn al-Zarqāllu](#) (Andalusia, ca. 1070), who seems to have relied on his predecessor Šā'id al-Andalusī). The theory of trepidation continued to occupy certain Muslim scholars (in the late period mainly in the Maghrib), as it did European scholars well into the Renaissance.

Other significant Islamic modifications to Ptolemaic planetary models, devised to overcome the philosophical objections to the notion

of an equant and the problem of the variation in lunar distance inherent in Ptolemy's lunar model, belong to the later period of Islamic astronomy. There were two main schools, one of which reached its fullest expression in Maragha in northwestern Iran in the thirteenth century (notably with al-Ṭūsī and his colleagues) and Damascus in the fourteenth (with Ibn al-Shāṭir), and the other developed in Andalusia in the late twelfth century (with al-Bīṭrūjī). The latter tradition was doomed from the outset by a slavish adherence to (false) Aristotelian tenets and by mathematical incompetence. The former was based on sophisticated modifications to Ptolemy's models, partly inspired by new observations; Ptolemy himself would have been impressed by it, as have been modern investigators, for the tradition has been rediscovered and studied only in the latter half of this century. In the 1950s Kennedy discovered that the solar, lunar, and planetary models proposed by Ibn al-Shāṭir in his book *Nihāyat al-su'l* (the Final Quest Concerning the Rectification of Principles) were different from those of Ptolemy; indeed they were mathematically identical to those of Copernicus some 150 years later. In this work Ibn al-Shāṭir laid down the details of what he considered to be a true theoretical formulation of a set of planetary models describing planetary motions, and actually intended as alternatives to the Ptolemaic models. He maintained the geocentric system, whereas Copernicus proposed a hypothesis, which he was unable to prove, that the sun was at the center of things. Nevertheless this important discovery raised the interesting question of whether Copernicus might have known of the works of the Damascene astronomer. Since the 1950s we have progressed to a new stage of inquiry: we now know that there was a succession of Muslim astronomers from the eleventh to the sixteenth century who concerned themselves with models different from those of Ptolemy, all designed to overcome what were seen as flaws in them. The question we may now ask is: was Copernicus influenced by any of these Muslim works? The answer is unsatisfactory, namely, that he must have been; definitive proof is, however, still lacking.

Mathematical Astronomy: The Tradition of the *Zijes*

The Islamic *zīj*es constitute an important category of astronomical literature for the historian of science, by virtue of the diversity of the topics dealt with, and the information that can be obtained from the tables. Kennedy (1956) published a survey of about 125 Islamic *zīj*es. We now know of close to 200, and material is available for a revised version of Kennedy's *zīj* survey. To be sure, many of these works are lost, and many of the extant ones are derived from other *zīj*es by modification, borrowing, or outright plagiarism. Nevertheless, there are enough *zīj*es available in manuscript form to reconstruct a reasonably accurate picture of Muslim activity in this field.

Most *zīj*es consist of several hundred pages of text and tables; the treatment of the material presented may vary considerably from one *zīj* to another. The following topics are handled in a typical *zīj*:

1. Chronology
2. Trigonometry
3. Spherical astronomy
4. Solar, lunar, and planetary mean motions
5. Solar, lunar, and planetary equations
6. Lunar and planetary latitudes
7. Planetary stations
8. Parallax
9. Solar and lunar eclipses
10. Lunar and planetary visibility
11. Mathematical geography (lists of cities with geographical coordinates), determination of the direction of Mecca
12. Uranometry (tables of fixed stars with coordinates)
13. Mathematical astrology

As noted above, by the eighth century a number of Arabic *zīj*es had been compiled in India and Afghanistan. These earliest examples, based on Indian and Sasanian works, are lost, as are the earliest examples compiled at Baghdad in the eighth century. With the *zīj*es compiled in Baghdad and Damascus in the early ninth century under the patronage of the Caliph *al-Ma'mūn*,

we are on somewhat firmer ground. These follow either the tradition of Ptolemy's *Almagest* and *Handy Tables* or the Indian tradition. Manuscripts exist of the *Mumtaḥan Zīj* of *Yaḥyā ibn Abī Maṣṣūr* and the Damascus *Zīj* of Ḥabash, each of which was based on essentially Ptolemaic theory rather than Indian. The *Zīj* of *al-Khwārizmī*, based mainly on the Persian and Indian traditions, has survived only in a Latin translation of an Andalusian recension. Amongst the most important and influential later works of this genre are: the *ṣābi' Zīj* of *al-Battānī* of Raqqa, ca. 910; the *ḥākīmī Zīj* of Ibn Yūnus, compiled in Cairo at the end of the tenth century; the *zīj* called *al-Qānūn al-Maṣ'ūdī* by al-Bīrūnī, compiled in Ghazna about 1025; the *Zīj* of Ibn Ishāq, compiled in Tunis, ca. 1195; the *I lkhānī Zīj* of *Naṣīr al-Dīn al-Ṭūsī*, prepared in Maragha in northwestern Persia in the mid-thirteenth century; and the *Sulṭānī Zīj* of Ulugh Beg from early fifteenth century Samarkand.

Although the *zīj*es are amongst the most important sources for our knowledge of Islamic mathematical astronomy, it is important to observe that they generally contain extensive tables and explanatory text relating to mathematical astrology as well. Islamic astrological texts form an independent corpus of literature, mainly untouched by modern scholarship. Often highly sophisticated mathematical procedures are involved. It should also be pointed out that in spite of the fact that astrology was anathema to Muslim orthodoxy, it has always been (and still is) widely practiced in Islamic society.

All early Islamic astronomical tables have entries written in Arabic alphanumerical notation (*abjad*) and expressed sexagesimally, i.e., to base 60. A number written in letters equivalent to "23 30 17 s" (Ulugh Beg's value for the obliquity) stands for $23 + 30/60 + 17/3,600$, i.e., $23^\circ 30' 17''$. In sexagesimal arithmetic, more so than in decimal arithmetic, it is useful to have a multiplication table at hand, and such tables, with 3,600 or even 216,000 entries, were available.

Already in the early ninth century Muslim astronomers had restyled the cumbersome Indian sine function using the Greek base 60 (which the Greeks had used for their even more cumbersome

chord function). Likewise the Indian shadow functions, unknown in Greek astronomy, were adopted with different bases (12, 6, $6\frac{1}{2}$, and 7, and also 60, and occasionally 1). Most *zīj*es contain tables of the sine and (co)tangent function for each whole, or half, or quarter degree of arc. Entries are generally given to three sexagesimal digits, corresponding roughly to five decimal digits. However, certain Muslim scholars compiled more extensive sets of trigonometric tables that were not included in *zīj*es. In the early tenth century al-Samarqandī prepared a set of tables of the tangent function with entries to three sexagesimal digits for each minute of arc. Later in the same century Ibn Yūnus tabulated the sine function to five sexagesimal digits, equivalent to about nine decimal digits, for each minute of arc, also giving the differences for each second. He also tabulated the tangent function for each minute of arc, and the solar declination for each minute of solar longitude. His trigonometric tables were not sufficiently accurate to warrant this number of significant figures, and indeed over four centuries were to elapse before the compilation in Samarqand of the magnificent trigonometric tables in the *Sulṭānī* ► *Zīj* of Ulugh Beg, which display the values of the sine and tangent to five sexagesimal digits for each minute of argument and are generally accurate in the last digit.

Planetary Tables and Ephemerides

Given the Ptolemaic models and tables of the mean motion and equations of the sun, moon, and planets were available to Muslim astronomers in the *Almagest* and *Handy Tables*, or the corresponding tables based on Indian models that exemplify the *Sindhind* tradition, Muslim astronomers from the ninth to the sixteenth century sought to improve the numerical parameters on which these tables were based. Most of the leading Muslim astronomers of the early period made solar observations and computed new solar equation tables. Ibn Yūnus is the only astronomer from the first four centuries of Islam known to have compiled a new set of lunar equation tables. The majority of Islamic planetary

equation tables are Ptolemaic, and where exceptions do occur, such as in the tables of Ibn al-Aʿlām and Ibn Yūnus for Mercury, we find that they are based on a Sasanian parameter rather than on any new observations.

Ptolemy used the same data as Hipparchus for his determination of the solar apogee and hence obtained the same result. The Muslims thus inherited the notion that the solar apogee is fixed with respect to the fixed stars (although the planetary apogees move with the motion of precession), and it is to their credit that their earliest observations established that the solar apogee had moved about 15° since the time of Hipparchus. Most early Muslim astronomers accepted the *Mumtaḥan* value of 1° in 66 Persian years (actually a parameter attested in earlier Persian sources) for both precession and the motion of the apogees. Ibn Yūnus possessed all the necessary data that could be used to demonstrate that the motion of the solar apogee is not the same as the motion due to precession, but he chose to use the same value for both, 1° in $70\frac{1}{4}$ Persian years, which happens to be remarkably close to the actual rate of precession. ► *Al-Bīrūnī* (Central Asia, ca. 1025) seems to have been the first to distinguish the proper motion of the solar apogee from the motion of precession (this discovery is sometimes erroneously attributed to al-Battānī). It was ► *Ibn al-Zarqāllu* (Andalusia, ca. 1070) who was the first to assign a numerical value to both motions, although he also subscribed to the theory of trepidation.

All Islamic *zīj*es contained tables of mean motions and equations for computing solar, lunar, and planetary positions for a given time. Some of the equation tables are arranged in a form more convenient for the user (so that one simply has to enter the mean motions, and calculations are avoided). Auxiliary tables were sometimes available for generating ephemerides without the tedious computation of daily positions from mean-motion and equation tables. From the ninth to the nineteenth centuries Muslim astronomers compiled ephemerides displaying solar, lunar, and planetary positions of each day of the year, as well as information on the new moons and astrological predictions resulting from the

position of the moon relative to the planets. Al-Bīrūnī described in detail how to compile ephemerides in his astronomical and astrological handbook *al-Taḥḥīm fī ṣināʿat al-tanjīm* (Instruction in the Art of Astrology). Manuscripts of ephemerides had a high rate of attrition since the tables could be dispensed with at the end of the year: the earliest complete extant examples are from fourteenth century Yemen, discovered in Cairo in the 1970s and still unpublished; on the other hand, literally hundreds of ephemerides survive from the late Ottoman period.

Stellar Coordinates and Uranography

Most *zīj*es contain lists of stellar coordinates in either the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course) or the equatorial systems, or occasionally in both. A survey of the stellar coordinates in Islamic *zīj*es would be a valuable contribution to the history of Islamic astronomy, and could help to determine the extent to which original observations were made by Muslim astronomers. An impressive amount of research on Arabic star names and their later influence in Europe has been conducted in the last few years by Paul Kunitzsch.

In his *ṣuwar al-kawākib* (Book of Constellation Figures) the tenth century Shiraz astronomer ► al-Šūfī presented lists of stellar coordinates as well as illustrations of the constellation figures from the Hellenistic tradition and also information on the lunar mansions following the Arab tradition. Later Islamic works on uranography are mostly restricted to Persian and Turkish translations of al-Šūfī, although some astrological works also contain illustrations of the constellations that have recently attracted the attention of historians of Islamic art.

Spherical Astronomy and Spherical Trigonometry

Most *zīj*es contain, in their introductory text, the solutions of the standard problems of spherical

astronomy, such as, to give only one example, the determination of time from solar and stellar altitude. Rarely any explanation given of how the formulae outlined in words in the text were derived. There were two main traditions. In the first, the problems relating to the celestial sphere are reduced to geometric or trigonometric problems on a plane. The construction known as the analemma was a singularly powerful tool for solutions of this kind. In the second, the problems are solved by applications of rules of spherical trigonometry. Both techniques are ultimately of Greek origin, and Muslim scholars made substantial contributions to each.

There is some confusion about these contributions in the modern literature. It has been assumed by modern writers that when a medieval writer used a medieval formula that is mathematically equivalent to the modern formula derived by a specific rule of spherical trigonometry, the medieval scholar must have known the equivalent of the modern rule of spherical trigonometry. In fact, however, the medieval formula may have been derived without using spherical trigonometry at all. The first known Islamic treatise dealing with spherical trigonometry independently of astronomy is by the eleventh century Andalusian Ibn Muʿādh. The contributions to spherical astronomy by scholars such as Thābit ibn Qurra, ► al-Nayrīzī, Abu'l-Wafā' al-Būzajānī, ► al-Khujandī, Kūshyār ibn Labbān, ► al-Sijzī, and Abū Naṣr are outlined in the recently rediscovered *Maqālīd fī 'ilm al-hay'a* (Keys to Astronomy) of ► al-Bīrūnī, also from the eleventh century.

Already in the work of Ḥabash in the mid-ninth century we find a Muslim astronomer at ease with both spherical trigonometrical methods and analemma constructions for solving problems of spherical astronomy. In the *Zīj*es of scholars of the caliber of Ibn Yūnus and al-Bīrūnī we find various methods for solving each of the standard problems of medieval spherical astronomy. The auxiliary trigonometric tables compiled by such scholars as Ḥabash, Abū Naṣr (Khwarizm, ca. 1000), and al-Khalīlī (Damascus, ca. 1360) for solving all of the problems of spherical astronomy for any latitude are a remarkable testimony to their mastery of the subject.

Observation Programs and Regional Schools of Astronomy: Al-Ma'mūn's Circle

In the early ninth century the Abbasid Caliph ► al-Ma'mūn patronized observations first in Baghdad and then in Damascus, gathering the best available astronomers to conduct observations of the sun and moon. Some of the results were incorporated into a ► zīj called *al-Mumtaḥan*, "tested," although the details of the activities at the two observation posts are somewhat confusing. The *Mumtaḥan Zīj* was apparently compiled in Baghdad by ► Yahyā ibn Abī Maṣṣūr, but upon his death, according to Ḥabash, the Caliph ordered his colleague Khālīd al-Marwarrūdhī to prepare some new instruments and conduct a 1-year program of solar and lunar observations in Damascus in order to compile a new zīj. According to Ḥabash this was done, but no such zīj is otherwise known to have been prepared before Ḥabash's own *Damascus Zīj*. Also simultaneous observations of a lunar eclipse were conducted at Baghdad and Mecca, and the longitude difference used together with the newly measured latitudes of the two localities to find the *qibla* at Baghdad.

These observations, like later ones, were mainly directed towards determining the local latitude and current value of the obliquity, and towards deriving improved parameters for the Ptolemaic planetary models and more accurate star positions. The armillary sphere, the meridian quadrant, and the parallactic ruler were known to the Muslims from the *Almagest*, and they added new scales and other modifications, often building larger instruments even when smaller ones would have sufficed. Our knowledge of the instruments used by al-Ma'mūn's astronomers is meager. An armillary sphere used by Yahyā in Baghdad was said to display markings for each 10 min of arc, but even contemporary astronomers were not impressed by the precision of the results obtained using it. A mural quadrant made of marble with a radius of about 5 m was used in Damascus, as well as a vertical gnomon made of iron standing about 5 m high. Al-Ma'mūn also patronized measurements of the longitude

difference between Baghdad and Mecca in order to establish the *qibla* at Baghdad properly, as well as measurements of the length of 1° of terrestrial latitude.

Other Observational Programs

Besides the officially sponsored observations conducted in Baghdad and Damascus in the early ninth century, there are numerous instances of other series of observations conducted in different parts of the Muslim world.

The two brothers called ► Banū Mūsā made observations in their own house in Baghdad and also in nearby Samarra about 30 years after the *Mumtaḥan* observations. They also arranged for simultaneous observations of a lunar eclipse in Samarra and Nishapur in order to determine the difference in longitude between the two cities. In view of their proficiency in mathematics, it is most unfortunate that neither of the two zījes compiled by them has survived.

► Al-Battānī carried out observations during the period 887–918 in Raqqa in northern Syria. He appears to have financed his observational activity himself, and although we have no description of the site where he made his observations, the instruments mentioned in the zīj based on his observations include an armillary sphere and mural quadrant, as well as a parallactic ruler, an astrolabe, a gnomon, and a horizontal sundial.

The observational activities of the Baghdad family known as the Banū Amājūr were almost contemporaneous with those of al-Battānī in Raqqa. Father and two sons, and also a freed family slave, all made observations and each compiled a ► zīj, none of which survives. In the accounts of their ► eclipse observations recorded by Ibn Yūnus it appears that the place where they conducted their observations had some kind of a balcony fitted with slits for observation, but the details are obscure. A particularly interesting account of a solar eclipse in the year 928 that they observed by reflection in water includes a remark that the altitude of the sun was measured on an instrument marked for each third of a degree.

A large mural quadrant was erected at Rayy (near modern Tehran) about the year 950, but we have information only on its use to establish the local latitude and obliquity of the ecliptic. In Shiraz not long thereafter, ► [al-Šūfī](#) used an armillary sphere with a diameter of about 5 m to derive the same parameters and to “observe” equinoxes and solstices. Al-Šūfī is best known for his work on the fixed stars, but it seems that this was based more on “observation,” looking at the heavens with the naked eye, than on “measurement,” looking at the heavens with precision instruments and making estimates of positions. Another contemporary astronomer who conducted observations on which we have no information other than the main parameters of his *zīj* was Ibn al-A‘lam.

In the late tenth century the distinguished mathematician and astronomer Abu’l-Wafā’ al-Būzajānī made observations in Baghdad. Most of these appear to have been directed towards the determination of the solar parameters, and the obliquity of the ecliptic and the latitude of Baghdad, although Abu’l-Wafā’ also collaborated with ► [al-Bīrūnī](#) in Khwārizm (modern Khiva in Turkmenistan) on the simultaneous observation of a lunar eclipse in the year 997. We have no information on the nature of the site where Abu’l-Wafā’ made his observations, other than its location in a specific quarter of Baghdad.

Contemporaneous with the activity of Abu’l-Wafā’ was the establishment in 988 of an observatory in the garden of the Baghdad residence of the Buwayhid ruler Sharaf al-Dawla. The organization of a building and program of observations was entrusted to Abū Sahl al-Qūhī, a mathematician of considerable standing. We know from contemporary historical records that a special building was erected for the observations, which in turn were witnessed by “judges, scientists and scholars of note, astronomers, and engineers.” In view of the favorable conditions under which this observatory was established, and the competence of its director, it is somewhat surprising that the two recorded “observations” that were witnessed by so many dignitaries were the entry of the sun into Cancer and Libra in the year 988. Al-Bīrūnī

describes the main instrument that was constructed as a hemisphere of radius 12.5 m on which the solar image was projected through an aperture at the center of the hemisphere. Activity at the observatory stopped in 989 with the death of Sharaf al-Dawla, so that the institution lasted not much more than a year.

In 994 Abū Maḥmūd ► [al-Khujandī](#) made a measurement of the obliquity using a meridian sextant of about 20 m radius. This instrument was erected in Rayy, but al-Khujandī confessed to al-Bīrūnī that it was so large that the center of the sextant had become displaced from its intended position.

The Egyptian astronomer Ibn Yūnus made a series of observations of eclipses, conjunctions, and occultations, as well as equinoctial and solstitial observations. We are extremely fortunate to have not only his reports of these observations, but also his citations of earlier observations of the same kind made by individuals such as Ḥabash and the Banū Amājūr. Ibn Yūnus’ purposed in making these observations and recording them in the introduction to his ► [Zīj](#) is somewhat obscured by the fact that he does not list those observations or present those calculations with which he derived his new solar, lunar, and planetary parameters. Neither does he mention any locations for his observations other than his grandfather’s house in Fustat and a nearby mosque in al-Qarāfa. The popular association of Ibn Yūnus with an observatory on the Muqāṭṭam Hills outside Cairo is, as Aydm Sayili has shown, a myth. Nevertheless, Ibn Yūnus mentions at least one instrument, probably a meridian ring, that was provided by the Fatimid Caliphs al-‘Azīz and al-ḥākīm. In a later medieval Egyptian source Ibn Yūnus is reported to have received 100 dinars a day from al-ḥākīm, and it may be that such extremely high payments were made to Ibn Yūnus when he was making satisfactory astrological predictions for the Caliph. Al-ḥākīm made an abortive attempt to find an observatory in Cairo, but this was after the death of Ibn Yūnus in 1009. At some time during his reign there was an armillary sphere in Cairo with nine rings, each large enough that a man could ride through them on horseback.

The observations of ► *al-Bīrūnī* were conducted between 990 and ca. 1025 in several localities between Khwārizm and Kabul. His recorded observations include determinations of equinoxes and solstices, eclipses, and determinations of the obliquity and local latitude.

The corpus of tables known as the *Toledan Tables* was compiled in the eleventh century, based on observations directed by Ṣāʿid al-Andalusī and continued by ► *Ibn al-Zarqāllu*. Only the mean motion tables in this corpus of tables are original; most of the remains were lifted from the *zīj*es of ► *al-Khwārizmī* and ► *al-Battānī*.

In the thirteenth century there was a substantial observational program at Maragha. The results are impressive only in so far as theoretical astronomy is concerned. Otherwise the trigonometric and planetary tables in the major production of the Maragha astronomers were modified or lifted in toto from earlier sources. This is not a happy outcome for a generously endowed observatory fitted with the latest observational instruments, known to us from texts. In the early fifteenth century the scene had moved to Samarkand in Central Asia: there, a group of astronomers, directed by the astronomer-prince Ulugh Beg, did impressive work. Only the 40-m meridian sextant survives from the observatory. These men produced a set of tables which it would be foolish to judge before they have been properly studied. The same is true for the short-lived observatory in Istanbul under the direction of Taqīʿl-Dīn (1577).

Regional Schools of Astronomy

After the tenth century they developed regional schools of astronomy in the Islamic world, with different interests and concentrations. They also had different authorities (for example, in the furthest East *al-Bīrūnī* and *al-Tūsī*, and in Egypt *Ibn Yūnus*). The main regions were Iraq, Iran and Central Asia, Muslim Spain, Egypt and Syria, the Yemen, the Maghrib, and later also the Ottoman lands. Only recently have the complex tradition of Muslim Spain (tenth to

fourteenth centuries), the colorful tradition of Mamluk Egypt and Syria (thirteenth to early sixteenth centuries), the distinctive tradition of Rasulid Yemen (thirteenth to sixteenth centuries), and the staid tradition of the Maghrib (twelfth to nineteenth centuries) has been studied. The traditions of Ottoman Turkey and Mogul India are currently being researched.

Transmission to Europe

The Europeans learned of Islamic astronomy mainly through Spain, a region where, because of political problems and the difficulty of communications, the most up-to-date writings were not always available. This explains, for example, how it came to pass that the Europeans came across two major works of Muslim astronomers from the East, *al-Khwārizmī* and *al-Battānī*, at a time when these works were no longer widely used in the Islamic East. It also explains why so few Eastern Islamic works became known in Europe. None of the Eastern Islamic developments to Ptolemy's planetary theory was known in Andalusia or in medieval Europe. *Al-Bīrūnī*'s unhappy attempt to develop planetary models confused Europeans for several centuries; he must be worth reading, they naively thought, because he was trying to reconcile Ptolemy with Aristotle. As far as astronomical timekeeping was concerned, this does not seem to have been of much concern to the Muslims in Spain; hence nothing of consequence was transmitted.

On the other hand, some early Eastern Islamic contributions, later forgotten in the Islamic East, were transmitted to Spain and thence to Europe; they have been considered European developments because evidence to the contrary has seemed to be lacking. A good example is the horary quadrant with movable cursor (the so-called *quadrans vetus*), which was invented in Baghdad in the ninth century and (at least in the version with the cursor) virtually forgotten in the Islamic East thereafter; it came to be the favorite quadrant in medieval Europe. What, if any, astronomical knowledge was transmitted through Islamic Sicily remains a mystery, and

nothing of consequence is known to have been learned about the subject by the Crusaders.

In the European Renaissance there was no access to the latest Islamic works. So the Europeans contented themselves with new editions of the ancient Greek works, with occasional, almost nostalgic, references to Albategnius ► (al-Battānī), Azarquiel (al-Zarqāllu), Alpetragius ► (al-Bīṭrījī), and the like. A few technical terms derived from the Arabic, such as alidade, azimuth, almucantar, nadir, saphea, and zenith, and a few star names such as Aldebaran, Algol, Al-tair, and Vega, survived. When the Europeans did come to learn of some of the major Islamic works and to try to come to terms with them it was as orientalists and historians of astronomy, for by this time the Islamic materials other than observation accounts were of historical rather than scientific interest. Thanks to orientalists like the Sédillots in Paris, works that had been completely unknown to Europeans and mainly forgotten by Muslims were published, translated, and analyzed. Islamic astronomy was highly respected by such scholars and others, like the historian of astronomy Delambre, who, innocent of Arabic, took the trouble to read what his colleagues had written about the subject. However, Islamic astronomy, indeed Islamic science in general, received a blow below the belt from Duhem, a physicist and philosopher ignorant of Arabic who simply ignored what scholars like the Sédillots had written. His thesis, that the Arabs were incapable of scientific thought and that whatever merits their science may have had were due to the intellectually superior Greeks, still has many followers, but only amongst those ignorant of the research of the past 150 years.

In the period after ca. 1500 Islamic astronomy declined. All of the problems had been solved, some many times over. Much of the innovative activity had led into a cul-de-sac, from which it would not emerge until modern times, thanks to investigations of manuscripts and instruments. Not that interest in astronomy died out. From Morocco to India the same old texts were copied and studied, recopied, and restudied, usually different texts in each of the main regions, but there was no new input or output of any consequence. Astronomy continued to be used as the handmaiden of astrology, and for the regulation of

the calendar and the prayer times. Where there was innovation – such as, for example, in the remarkable device made in Isfahan ca. 1700 that correctly displays the direction and distance of Mecca for any locality – one must suspect the existence of an earlier tradition. However, the old traditions died hard, and Muslim astronomers for several centuries spent more time copying old treatises and tables than compiling new ones.

During the millennium beginning ca. 750 and especially in the period up to ca. 1050, although also in the period up to ca. 1500, Muslim astronomers did first-rate work, most of which was not known in medieval Europe at all. Those few Islamic works from the early period that were transmitted, notably the *zīj*es of ► al-Khwārizmī and al-Battānī (especially through the *Toledan Tables*) and the banal summary of the *Almagest* by ► al-Farghānī, convey only an impression of classical astronomy in Arabic garb. However, they were in no way representative of contemporary Islamic astronomy in the East, and whilst the Europeans labored for centuries to come to terms with them, Muslim astronomers were making substantial contributions to their subject that have only been revealed by modern scholarship.

There is a wealth of material relating to this subject that remains untouched. Very few Islamic astronomical works have been published or have received the attention they merit. Three out of close to 200 Islamic *zīj*es have been published in the optimum way (text, translation, and commentary). We have no published edition of the Arabic versions of the *Almagest* (except for the star catalogue), or of any Arabic recensions or commentaries. Many of the published Arabic scientific texts were printed in Hyderabad, most with no critical apparatus. Likewise most of the historically important Islamic astronomical instruments are still unpublished, although the catalogue currently in preparation in Frankfurt promises to make them better known.

In 1845 Sédillot, whose privilege it was to have access to the rich collection of Arabic and Persian scientific manuscripts in the Bibliothèque Nationale in Paris, wrote: “Each day brings some new discovery and illustrates the extreme importance of a thorough study of the manuscripts of

the East.” Sédillot also realized the importance of Islamic astronomical instruments. Given the vast number of manuscripts and instruments now available in libraries and museums elsewhere in Europe, the United States, and the Near East, and the rather small number of people currently working in this field, Sédillot’s statement is no less true today than it was a century and a half ago.

Astronomy in Tibet

Yukio Ōhashi

Tibetan astronomy is a living form of traditional astronomy, and is the basis of the Tibetan calendar which is used in Tibet and in Tibetan communities in India, and other places in the world.

There are four branches of Tibetan astronomical science (*rtsis*). The most important branch is *skar-rtsis* (star calculation) which is based on the *Kālacakra* astronomy of India. Another branch is *dbyanis-'char* which is based on Indian divination, *svarodaya*. Another is *nag-rtsis* (black calculation), based on Chinese astrology and natural philosophy, and the last branch is *rgya-rtsis* (Chinese calculation), based on the Shixian calendar of China.

Indo-Tibetan Astronomy

The Tibetan *Tripitaka* is a collection of Tibetan translations of Buddhist works, some of which include astronomical information. There is a Tibetan translation of the *Śārdūlakarṇa-avadāna*, which is a Buddhist work in which early Indian astronomy and astrology of the Vedāṅga period, the post-Vedic period before Greek influence, are mentioned. There is also a Tibetan translation of an early Indian astrological text ascribed to Sage Garga. Astronomical knowledge in these texts is from an early period, and not of *skar-rtsis*. The most important texts from an astronomical point of view are the Tibetan translation of the *Kālacakra-tantra* and its commentary, *Vimalaprabhā*.

Kālacakra-yāna Buddhism is the last stage of Esoteric Buddhism in India. Its most fundamental text is the *Kālacakra-tantra*. It is not known when and where it was composed. Some people say it was introduced into Tibet in AD 1027, and was introduced into India from Central Asia 60 years before. I believe that it was composed in the eleventh century, because the year 1027 is used as the beginning of the 60-year cycle (*br̥haspaticakra*) in the text itself. I also believe that it was composed in India, because it adopts the Hindu system of astronomy without any apparent influence of Chinese or other astronomy.

According to the commentary *Vimalaprabhā*, there was the original text or *Mūla-tantra*, where the *Siddhānta* system of astronomy was explained, and the text on which it comments is the abridged text or *Laghu-tantra*, where the *Karaṇa* system of astronomy is explained. The *Mūla-tantra* is not extant, and it is difficult to say whether it actually existed as a whole or not, but some fragments are quoted in the *Vimalaprabhā*. The *Siddhānta* system of astronomy is called *grub-rtsis* in Tibetan, and the *Karaṇa* system is called *byed-rtsis*. In Tibetan astronomy, these two systems are basically the same, and only the length of a year and a month are different. In the *Siddhānta* system, one sidereal year = 365.270645 days and one synodic month = 29.530587 days. In the *Karaṇa* system,

a sidereal year = 365.258675 days, while a synodic month = 29.530556 days.

In the Tibetan calendar, there are 2 intercalary months for 65 ordinary months. This is harmonious with the *Siddhānta* system, but not with the *Karaṇa* system. The *grub-rtsis* is usually followed now.

Since about the twelfth century, the *Kālacakra* calendar has been followed in Tibet. In the fourteenth century, a comprehensive treatise of *Kālacakra* astronomy entitled *mKhas-pa-dga'-byed* (AD 1326) was composed by an encyclopaedic scholar Bu-ston Rin-chen-grub (1290–1364). After Bu-ston, lHun-grub-rgya-mtsho wrote the *Pad-dkar-ḡal-luṅ* (AD 1447), and his system was developed as the Phug school. The most famous work of this school is the *Vaidūrya dkar-po* (AD 1683) written by Saṅs-rgyas-rgya-mtsho, who was the regent of the fifth Dalai Lama. Another famous work is the *Ñin-byed-snañ-ba* (AD 1714) of Dharmaśīr.

There is another school, mTshur-phu, whose fundamental text is the *Ñer-mkho-bum-bzan* (AD 1732) written by Karma Ñes-legs-bstan-'dzin.

Let us use astronomical calculation in the *mKhas-pa-dga'-byed* as a case study. It is one of the earliest treatises of the *skar-rtsis* branch of Tibetan astronomy and will give a general idea of *skar-rtsis*. As *skar-rtsis* is based on *Kālacakra* astronomy, it is similar to Hindu astronomy. First, mean motions of the planets are calculated, and then the equation of the center and the epicyclic correction are applied. The operation of the equation of the center (Sanskrit: *manda-karman*) is called *dal-ba'i-las* in Tibetan, and the operation of the epicyclic correction (Sanskrit: *śīghra-karman*) is called *myur-ba'i-las*.

Three kinds of days are used. They are *ñin-ḡag* (Sanskrit: *sāvana-dina*), *tshes-ḡag* (Sanskrit: *tithi*), and *khyim-ḡag* (Sanskrit: *saura-dina*). A *ñin-ḡag* is a civil day measured from sunrise to sunrise. A mean *tshes-ḡag* is a 13th part of a synodic month. The equation of the center of the sun and moon are applied so as to make a *tshes-ḡag* correspond to the change of 12° of the longitudinal difference between the sun and moon. A mean *khyim-ḡag* is a 360th part of 1 year.

The ecliptic is divided into 12 *khyim* (Sanskrit: *rāśi*) or zodiacal signs, and also into 27 *rgyu-skar* (Sanskrit: *nakṣatra*) or lunar mansions. Each day as well as *rgyu-skar* is divided into 60 *chu-tshod* (Sanskrit: *nāḡḡ*). One *chu-tshod* is further divided into 60 *chu-srañ* (Sanskrit: *vināḡḡ*). One *chu-srañ* is divided into six *dbugs* (Sanskrit: *prāṇa*).

The mean motion of the sun and moon is calculated from the following simple formulae, which correspond to the *grub-rtsis* system:

$$\text{Length of a } khyim-ḡag = \text{length of a } tshes-ḡag \times \left(1 + \frac{2}{65}\right)$$

$$\text{Length of a } tshes-ḡag = \text{length of a } ñin-ḡag \times \left(1 + \frac{1 + \frac{1}{707}}{64}\right)$$

The equation of the center of the sun is given for each zodiacal sign. Twelve zodiacal signs are divided into four quadrants. Then 6/135, 4/135, and 1/135 of the mean daily motion of the sun are subtracted from or added to the mean daily motion of the sun in each sign. The variables 6, 4, and 1 are called *dal-rkañ* (slow step). The ecliptic is divided into the first half (*rim-pa*) and the second half (*rim-min*). The first as well as the second half is further divided into the first part (*sña-rkañ*) and the second part (*phyi-rkañ*). So, one part consists of three signs. The first point of the first half is the apogee.

This *dal-rkañ* is, in fact, the difference between the mean motion and the true motion of the sun during one zodiacal sign's movement of the mean sun in terms of *chu-tshod*. Hence, the maximum equation is the total of the variables, that is 11 *chu-tshod* or 2°26'40". The solar apogee is located at the first point of Cancer in this system.

One anomalistic month is roughly considered as 28 *tshes-ḡag*, and a correction is applied to the length of each *tshes-ḡag*. This correction is called *zla-ba'i-myur-rkañ* (fast step of the moon). The word *myur* (fast) shows that it was considered to be the epicyclic correction rather than the equation of center. Since the period of 28 *tshes-ḡag* is a

little longer than the actual anomalistic month, a special correction is also applied so as to diminish the period of 28 *tshes-žag* at the rate of one *tshes-žag* per 3,780 *tshes-žag*. So, one anomalistic month becomes about 27.55459 civil days.

One anomalistic month is divided into four quadrants, each of which consists of seven *tshes-žag*. Then 5, 5, 5, 4, 3, 2, and 1 *chu-tshod* are added to or subtracted from the length of each *tshes-žag*. These values were probably originally meant to be the difference between the mean motion and the true motion of the moon during one *tshes-žag* in terms of *chu-tshod*. Since the time interval during which the moon moves the arc of one *chu-tshod* is about 1.01 *chu-tshod*, this was considered to be one *chu-tshod*, and the same value was used for the correction of the length of a *tshes-žag*. The maximum equation is the total of the variables, that is 25 *chu-tshod* or $5^{\circ}23'20''$.

Five planets are divided into *ži-ba'i-gza'* which corresponds to inner planets, and *drag-gza'* which corresponds to outer planets. The sidereal period (*dkyil-'khor*) of each planet is given as follows:

Mercury (*lhag-pa*): 87 days 58 *chu-tshod* 12 *chu-srai*

Venus (*pa-saṅs*): 224 days 42 *chu-tshod*

Mars (*mig-dmar*): 687 days

Jupiter (*phur-bu*): 4,332 days

Saturn (*spen-pa*): 10,766 days

Just as in the case of the sun, *dal-rkañ* (slow step) for each zodiacal sign is given for each planet. The mean daily motion of each planet in the case of outer planets, or of the sun in the case of inner planets, is corrected as follows.

Corrected daily motion = $A \mp A(d/135)$, where A is the mean daily motion, and d is *dal-rkañ*. The value of *dal-rkañ* for each planet is:

Mars: 25, 18, and 7

Mercury: 10, 7, and 3

Jupiter: 11, 9, and 3

Venus: 5, 4, and 1

Saturn: 22, 15, and 6

The total of the value of *dal-rkañ* is the maximum equation in terms of *chu-tshod*. The maximum equation of each planet is:

Mars: 50 *chu-tshod* or $11^{\circ}6'40''$

Mercury: 20 *chu-tshod* or $4^{\circ}26'40''$

Jupiter: 23 *chu-tshod* or $5^{\circ}6'40''$

Venus: 10 *chu-tshod* or $2^{\circ}13'20''$

Saturn: 43 *chu-tshod* or $9^{\circ}33'20''$

The longitude of the apogee of each planet in this system is Mars: $126^{\circ}40'$, Mercury: 220° , Jupiter: 160° , Venus: 80° , and Saturn: 240° .

The “parameter of step” (*rkañ-'dzin*) is used to count steps of epicyclic correction. The period of 60 *chu-tshod*’s change of the “parameter of step” is considered one step. Sixty *chu-tshod* correspond to 1 lunar mansion, and there are 27 lunar mansions, so 1 cycle consists of 1,620 *chu-tshod*. One cycle is divided into 2 halves, and each consists of 14 steps. The 14 step of the first half and the first step of the second half consist of 30 *chu-tshod* only.

In the case of the outer planets, daily motion of the “parameter of step” is the mean daily motion of the sun minus the daily motion of the planet which has been corrected by its equation of center. In the case of the inner planets, the daily motion of the “parameter of step” is the daily motion of “parameter of fast step” (*myur-rkañ-'dzin*) minus the true daily motion of the sun. The “parameter of fast step” is, in fact, the daily motion of the planet’s revolution, because it is defined as the quotient of 1,620 *chu-tshod* divided by the planet’s sidereal period. The variable of the epicycle correction is given as *myur-rkañ* (fast step) for each step.

The method of the correction is as follows: let M be the true daily motion of the planet, D the daily motion of the planet in the case of an outer planet and the daily motion of the sun in the case of an inner planet, both of which have been corrected by the equation of center of the planet itself, K the daily motion of the “parameter of step,” and m the *myur-rkañ*. Then, for the steps from the first step to the 13 step of the first half and from the second step to the 14 step of the

second half, the following equation gives the true daily motion of the planet

$$M = D \pm K \frac{m}{60}.$$

For the 14 step of the first half and the first step of the second half, the following equation is used

$$M = D \pm K \frac{m}{30}.$$

The first half (*rim-pa*) as well as the second half (*rim-min*) are further divided into the first part (*sña-rkañ*) and the second part (*phyi-rkañ*). The correction is plus in the first part of the first half and the second part of the second half, and minus in the second part of the first half and the first part of the second half.

The values of *myur-rkañ* for each planet are shown in Table 1. The values are arranged for the first half. In the second half, the same value is used in reverse order.

The total of the value of *myur-rkañ* in one part is the maximum epicyclic correction in terms of *chu-tshod*. The maximum correction of each planet is:

Mars: 182 *chu-tshod* or 40°26'40"

Mercury: 97 *chu-tshod* or 21°33'20"

Jupiter: 52 *chu-tshod* or 11°33'20"

Venus: 208 *chu-tshod* or 46°13'20"

Saturn: 28 *chu-tshod* or 6°13'20"

In a paper written in 1986, I compared the astronomical constants used by Bu-ston with those of some schools of Hindu astronomy, and pointed out that they are close to those of the Ārdharātriśa school of Hindu astronomy.

Sino-Tibetan Astronomical Science

The *nag-rtsis* is said to have been introduced into Tibet from China in the seventh century. It is based on Chinese astrology and natural philosophy. According to the *Zla-ba'i-'od-zer* (AD 1684) of Dharmasrī, a popular work of *nag-rtsis*, the most fundamental elements of the *nag-rtsis* are as follows.

Astronomy in Tibet, Table 1 The values of *myur-rkañ* for each planet

Planet	First part	Second part
Mars	24, 23, 23, 23, 21, 21, 18, 15, 11, and 3	11, 38, 80, and 53
Mercury	16, 16, 15, 14, 13, 11, 7, 5, and 0	4, 11, 20, 28, and 34
Jupiter	10, 10, 9, 8, 6, 6, 2, and 1	3, 6, 9, 11, 16, and 7
Venus	25, 25, 25, 24, 24, 22, 22, 18, 15, and 8	6, 30, 99, and 73
Saturn	6, 5, 5, 4, 4, 2, 2, and 0	2, 4, 5, 6, 8, and 3

1. *Khams* (also called '*byui-ba*'), which are the five elements of Chinese natural philosophy: wood, fire, earth, metal, and water.
2. *Lo-'gros*, which are 12 animals used to name each year of a 12-year cycle: rat, ox, tiger, rabbit, dragon, snake, horse, sheep, monkey, bird, dog, and boar. This 12-year system is the Chinese system, which is widely used in East Asia. The combination of the *khams* and *lo-'gros* is used to name each year of a 60-year cycle. This is also the Chinese system.
3. *Sme-ba*, which is the Chinese "nine stars" used for astrological purposes.
4. *sPar-kha*, which is eight symbols of Chinese natural philosophy, of which the most fundamental text is the famous Yijing (I Ching, Book of Changes).
5. *Zla-ba*, which is 12 months for each of which 12 animals are attributed. The first month of spring is a tiger, and so on.
6. *Tshes*, which is the date of the month.
7. *Dus-tshod*, which is a 12th part of a day, for each of which 12 animals are attributed. The midnight is rat, and so on.
8. *gZa'*, which is eight planets: the sun, moon, five planets, and *rāhu*. The *rāhu* (dragon's head, or the ascending node of the lunar orbit) is not Chinese, but of Indian origin.
9. *sKar-ma*, which is the Chinese 28 lunar mansions or lodges.

The *rgya-rtsis* is based on the Tibetan version (AD 1725) of the Mongolian translation (AD 1711) of the Chinese astronomical work

Xiyang xinfu suanshu (AD 1669) compiled in the Qing dynasty, which is the theoretical text on the Shixian calendar. The Shixian calendar is the last luni-solar calendar in China.

The traditional Tibetan calendar, which is based on the Phug school of *skar-rtsis*, is still used by Tibetan people. Also, several Tibetan astronomical texts are extant, and the process of astronomical calculation is explained in detail in these texts. More extensive study of Tibetan astronomy by historians of astronomy will be fruitful. In 1987, Chinese scholars Huang Mingxin and Chen Jiujin published a *skar-rtsis* text of epoch AD 1827, the *Rigs-ldan-sñin-thig* of Phyag-mdzod gsuñ-rab, with Chinese translation and astronomical commentary. This is a good introduction to Tibetan astronomy.

Astronomy of the Australian Aboriginal People

Roslynn D. Haynes

The Australian Aborigines were almost certainly the world's first astronomers. Their complex systems of knowledge and beliefs about the heavenly bodies have been handed down through song, dance, and ritual for some 40,000 years, predating by many millennia those of the Babylonians, the ancient Greeks, the Chinese, or the Incas. The legends which have survived, until very recently, within a virtually unchanged cultural context, show how natural phenomena, including celestial bodies and events, were assimilated by the Australian Aborigines into a holistic value system which was predicated on the close relationship of the individual with the whole natural world: It is significant, in this regard, that theirs was the only known culture with no myth of alienation from Nature, such as the expulsion from Eden of the Judeo-Christian tradition. On the contrary they believed that through their Great Ancestors of the Dreaming they, too, were continuing co-creators of the natural world. Hence they used their knowledge of the stars not only to predict and explain natural occurrences but also to provide celestial parallels with tribal experiences and behavioral codes.

The Aborigines' knowledge of the "crowded" southern sky was probably the most precise possible for people dependent on naked-eye astronomy. They made accurate observations, not only of first- and second-order stars, but also of the more inconspicuous fourth-magnitude stars. Pattern was apparently more important in recognition than brightness, for the Aborigines often identified a small cluster of relatively obscure stars while ignoring more conspicuous single stars in the vicinity. Thus the people of Groote Eylandt named as *Unwala* (the Crab) the small cluster of relatively insignificant (average magnitude 4.4) stars Sigma, Delta, Rho, Zeta and Eta

Hydrae, while disregarding the adjacent bright stars Procyon (α Canis Minoris) and Regulus (α Leonis) (magnitude 0.36 and 1.35, respectively) which are not part of an obvious group. Members of the Boorong tribe of the Mallee District of Victoria limited their identification procedures to linear patterns of three or more stars. Unlike the familiar Greek designations, based on a join-the-dot pictorial image, the Aborigines identified a group of stars with the whole cast of characters in a story, the relationship being conceptual rather than visual. Color was also an important factor in the aboriginal designation of stars. The Aranda tribes of Central Australia distinguish red stars from white, blue, and yellow stars. They classify the bright star Antares (α Scorpii) as *tataka indora* (very red) while the stars of the V-shaped Hyades cluster are divided into a *tataka* (red) group and a *tjilkera* (white) group. The former are said to be the daughters of the conspicuously red star Aldebaran (α Tauri).

The Aborigines also differentiated between the nightly movement of the stars from east to west and the more gradual annual shift of the constellations. From this latter displacement they devised a complex seasonal calendar based on the location of constellations in the sky, particularly at sunrise or sunset. The Aranda and Luritja tribes around Hermannsburg in Central Australia knew that certain stars lying to the south, namely *Iritjinga* and the Pointers of the Southern Cross, are visible throughout the year, although their position in the sky varies. This amounts to a realization that stars within a certain distance of the South Celestial Pole never fall below the horizon.

Yet what the Aborigines did with their astronomical knowledge was fundamentally different from the procedures of Western science. Tribal Aborigines paid no attention to two of the most basic concepts of western science, numeracy and temporality; they made no measurements of space or time, nor did they engage in even the most elementary mathematical calculations. Their observations of the stars were conducted for essentially pragmatic reasons. Either they were an attempt to discover predictive correlations between the position of the stars and other

natural events important to the survival of the tribe – the availability of specific foods or the onset of particular weather conditions, or they provided a system of moral guidance and education in tribal lore – a function regarded as equally necessary to the continuation of tribal identity.

As hunter – gatherers, dependent for their survival on a foreknowledge of environmental changes, the Aborigines noted the correlation between the movements and patterns of stars and changes in the weather or other events related to the seasonal supply of food. Thus the significance attributed to these sidereal occurrences varied with the diet and lifestyle of different tribes. On Groote Eylandt the appearance in the evening sky toward the end of April of Upsilon and Lambda Scorpii indicated that the wet season had ended and that the dry south-easterly wind or *marimariga* would begin to blow, causing changes in climate and animal behavior. At nearby Yirrkalla the appearance of Scorpio in the morning sky in early December heralded the arrival of the Malay fishermen who came in their canoes to collect trepang or *bêche de mer* which they sold to the Chinese. In winter, the most spectacular individual stars in the southern sky are Arcturus (α Bootis) and Vega (α Lyrae). When Arcturus could be seen in the eastern sky at sunrise, the Aborigines of Arnhem Land knew that it was time to harvest the spike-rush or *rakia*, a reed valuable for making fish traps and baskets for carrying food, and a local legend about Arcturus served as an annual reminder of this. On the other hand, amongst the *Boorong* tribe of the Mallee district of western Victoria, Arcturus was personified as *Marpeankurrk* the tribal hero who showed them where to find *bittur*, the pupa of the wood ant, a staple item of diet during August and September. The constellation Lyra represented the spirit of *Neilloan*, or the Mallee-hen who taught the tribe how to find its eggs, an important source of food in October. Other notable events, like the ripening of tubers and bulbs and the appearance of migratory birds and animals, were correlated with specific positions of Orion, the Pleiades and the Southern Cross at different seasons of the year. For the Pitjantjatjara tribe in the Western Desert, the appearance of the

Pleiades in the dawn sky in autumn was the sign that the annual dingo-breeding season had begun. Fertility ceremonies were performed for the dingoes, or native dogs, and some weeks later the tribe raided the lairs, culling and feasting on the young pups. The legends ensured that these nutritional associations were not forgotten and stressed their importance for the continuing survival of the race.

Equally important to the preservation of the tribe was its sense of identity, involving tribal beliefs orally transmitted across generations. These myths outlined the role of the Ancestors of the Dreaming in the scheme of the universe and the behavior appropriate to their descendants. Explanations of natural events which emphasized pattern, order, and laws, rather than unpredictable effects, reinforced the sense of an organic relationship between natural phenomena and social behavior. Many of these legends involved the constellations, so that the night sky provided a periodic reminder of the moral lessons enshrined in the myths.

Like all explanatory systems, including Western science, these legends represented attempts to understand, predict, and hence to obtain some control over the natural world. However, unlike the essentially analytical, materialistic, and particularizing approach of Western science, the underlying premise of all the aboriginal myths was a belief in the close spiritual unity of human beings, not only with other species, but also with inanimate objects. Astronomy was an integral part of the Aborigines' total philosophy about the natural world, so the legends emphasized the parallels between the personified heavenly bodies and their earthly counterparts, humanizing and integrating natural phenomena with tribal institutions and customs.

The meaning which a tribe attributed to the celestial bodies was conceptual rather than perceptual. It could not be understood by personal experience or by the intellect, but only through initiation into tribal lore which stressed the intimate, causal association between physical events and the human dramas of good and evil. Lessons about compassion, brotherhood, and respect for the land as Mother, the prohibition of incest and

adultery, and taboos on killing or eating totemic animals were nightly reinforced by being enacted in the sky world which thereby established the universal validity of the tribe's ethical laws.

The many and diverse aboriginal myths associated with the heavenly bodies include stories about the Sun, the Moon, the Milky Way, the Magellanic Clouds, Mars, Venus, and the several constellations which form distinctive patterns in the southern sky – notably the Southern Cross and its pointers, the Pleiades, Orion's Belt, Scorpio, Gemini, and Aldebaran. The following are a representative selection of these myths.

In most of the Aboriginal creation stories, the Sun is the life-giving spirit. Amongst the Murray River tribes the origin of the Sun is linked to the tossing of a giant emu egg into the sky where it struck a heap of dry wood and burst into flame, bringing light to the hitherto dark world. Thereupon, the Great Spirit *Baiaime*, seeing how much the world was improved by sunlight, decided to rekindle the woodpile each day.

In contrast to the ancient Greeks, the Amerind Indians and the Quechua Indians of Peru, all of whom designated the Sun as male and the Moon as female, whereas the Australian Aborigines represented the Sun as female and the Moon as male. In most areas, the Sun is regarded as a woman who daily awakes in her camp in the east and lights a fire to kindle the bark torch she will carry across the sky, thus providing the first light of dawn. She decorates herself with powder made from crushed red ochre, coloring the clouds red in the process. At evening she renews her powder in the western sky before beginning her long passage underground back to her camp in the east. It was probably this underground journey which was instrumental in the classification of the Sun as female, for her torch is thought to bring warmth and fertility to the interior of the Earth, causing the plants to grow. However, in Arnhem Land, where the Sun sets in the sea, she is thought to become a great fish, swimming under the Earth to return in the east next morning while the Moon becomes a fish, passing beneath the earth during the day.

The Moon, being male, is generally accorded greater status, and in many areas powers of death

and fertility are accorded to him. An eclipse of the Sun is interpreted as indicating that the Moon Man is uniting with the Sun Woman. Several legends have evolved to account for the Moon's cycles. In coastal areas the correlation between the phases of the Moon and the tides was noted. In Arnhem Land and Groote Eylandt, where high tides occur when the new or full Moon sets at sunset or sunrise, respectively, and low tides when the moon is in the zenith at sunrise or sunset, the local Aborigines believe that the high tides, running into the Moon as it sets into the sea, make it fat and round. (Although the new Moon may appear thin, they deduce from the faint outline of the full circle that it too is round and full of water.) Conversely, when the tides are low, the water pours from the full Moon into the sea below and the moon consequently becomes thin.

In most areas the Moon was regarded as more mysterious, and hence more dangerous, than the Sun. Because of the association of the lunar cycle with the menstrual cycle, the Moon was linked with fertility and young girls were warned against gazing at the Moon unless they wished to become pregnant.

The Milky Way was regarded by the Aborigines as a river in the Sky World, the large bright stars being fish and the smaller stars water-lily bulbs. Central Australian tribes believed that the Milky Way divided the sky people into two tribes and thus it served as a perpetual reminder that a similar equitable division of lands should be observed between neighboring tribes. Various legends regarding taboo marriages, adultery, and reminders to celebrate tribal heroes, many of them involving a moral lesson, have evolved in different areas to account for the formation of the Milky Way and the dark region, known to Europeans as the "Coal Sack."

A Queensland version of the origin of the Milky Way associates it with *Priepriggie*, an Orpheus-like hero, as famed for his songs and dances as for his hunting. When he disappeared, his people tried unsuccessfully to perform his dance until they heard singing in the sky. Then the stars, hitherto randomly dispersed, arranged themselves to the rhythm of *Priepriggie's* song.

Thus the Milky Way serves as a reminder that the tribal hero should be celebrated with traditional songs and dancing.

Because of its diagrammatic shape, the Southern Cross features in association with various characteristic objects in different areas. Around Caledon Bay on the east coast of Arnhem Land, it is taken to represent a stingray being pursued by a shark – the Pointers. On Groote Eylandt, where fish is the staple diet, the four stars of the Cross represent two brothers, the *Wanamoumitja* (Alpha and Beta Crucis), and their respective camp fires (Delta and Gamma Crucis) where they cook a large black fish (the Coal Sack) which they have caught in the Milky Way. The Pointers are their two friends, the *Meirindilja*, who have just returned from hunting. Desert tribes, on the other hand, see in the kite shape of the Cross the footprint of the wedge-tailed eagle *Waluwara* while the pointers represent his throwing stick and the Coal Sack his nest.

Venus, the Morning Star, was an important sign to the Aborigines, who arose at early dawn to hunt. It, too, was personified and frequently associated with death. Arnhem Land legends identify the home of the morning star, *Barnumbir*, as Bralgu, the Island of the Dead. Afraid of drowning, *Barnumbir* could be persuaded to light her friends across the sea at night only if she were held on a long string by two old women, who at dawn would pull her back to Bralgu and keep her during the day in a basket. Because of this connection, the morning star ceremony is important in the local rituals for the dead since a dead person's spirit is believed to be conducted by the star to *Bralgu*.

One of the most widespread Aboriginal myth cycles concerns the constellations of Orion and the Pleiades and these bear a striking similarity to the Greek story of the seven daughters of Atlas who, when pursued by Orion, flew into the sky as doves to form the constellation of the Pleiades. All identify them with a group of seven young women and nearly all portray them as fleeing from the amorous hunter Orion who, in some versions, is castrated as a punishment and warning to other potential wrongdoers. The whole cluster of Pleiades stories therefore forms part

of a much larger group of myths of sexual conquest and submission.

Amongst the Pitjantjatjara tribe, the practical connection between the dingo-breeding season and the appearance of the Pleiades in the dawn sky in autumn is preserved in a local legend. The *Kungkarungkara* or ancestral women kept dingoes to protect them from a man *Njiru* (Orion), but he succeeded in raping one of the girls, the obscure Pleiad, who died. Even though the women assumed their totemic form of birds and flew into the sky to escape from him, he defies their dingoes and follows the women across the sky, armed with a spear (the stars of Orion's Belt) which has ritual phallic significance. Like the Greek Orion, *Njiru* was also a hunter, and pairs of smaller stars which arise near the constellation of Orion are said to represent his footsteps as he pursues the *Kungkarungkara*.

At Yirrkalla on the coast of Arnhem Land, the constellation of Orion is regarded as a group of fisherman arriving from the east in a canoe with a turtle they have caught, while the Pleiades represent their wives in another canoe with two large fish. As they approached the shore a heavy storm capsized the canoes, drowning the people. All the representative stars are visible in the sky during the wet season – a warning against the dangers of fishing when storms are imminent. In north-eastern Arnhem Land the story carries the added moral that the fishermen drowned as a punishment for catching catfish, forbidden to this tribe by totemic law.

Although relatively insignificant to the naked eye, the Large and Small Magellanic Clouds feature in many aboriginal legends as the camps of sky people. On Groote Eylandt they are believed to be the camps of an old couple, the *Jukara*, grown too feeble to catch their own food. Other star people catch fish and lily bulbs for them in the Milky Way and bring them to the *Jukara* to cook on their fires. The space between the Clouds is their cooking fire, while the bright star Achernar (Alpha Eridani, magnitude 0.49) represents their meal. This story suggests a celestial model of compassion for the aged. At Yirrkalla the Magellanic Clouds are said to be the homes of two sisters. During the middle of the dry season

the elder sister (Large Cloud) leaves her younger sister (Small Cloud), but during the wet season she returns so that they can collect yams together. This story reflects the observed fact that at this latitude (12° S) only the Small Cloud is visible during most of the dry season (April to September), whereas both Magellanic Clouds can be seen during the wet season.

Meteors have been variously interpreted by different aboriginal tribes. In north-eastern Arnhem Land, because of their speed and unpredictability, they are believed to be spirit canoes carrying the souls of the dead to their spirit home in the sky. To the Tiwi tribe of Bathurst and Melville Islands, each is the single eye of the one-eyed spirit men, the *Papinjuwari*, who steal bodies and suck the blood of their victims, and their evil eyes are seen blazing as they streak across the sky looking for their prey. In other legends, meteors are associated with fire and linked to the waratah plant, *Telopea speciosissima*, a member of the Protea family, which is resistant to fire and whose brilliant red flowers seemed to the Aborigines like sparks from a fire. This was why, in the early years of white settlement, some Aborigines brought waratahs to the European blacksmiths: they identified the sparks from the anvil with the sparks from meteors and hence with the waratahs.

From this selection of star legends, it will be apparent that, with the possible exception of meteors (and even they can be regarded as recurrent events), the Aborigines' concern was not with extraordinary occurrences, but with the regular patterns of natural phenomena. The star legends served the purpose of integrating a potentially alien universe into the moral and social order of the tribe – by “humanizing” species and natural objects and ascribing to them behavior patterns and motivations which accorded with those of the tribal unit.

Such a philosophy serves a number of important social functions. In the first place it engenders a level of confidence about Man's place in the universe, not as a superior being but as an equal partner; in this it fulfils a role comparable to that of technology which also offers a level of some control over the environment. Secondly,

this philosophy cultivates respect for the inanimate world as well as the animate since, through the indwelling power of the Ancestors, all creatures and things partake of the same spiritual identity as Man himself. Thirdly, the legends provide a justification for the customs, rites, and morality of the tribe, since these are reflected and enacted in the Sky-world.

The aboriginal myths are not fatalistic as astrology purports to be. Although they link certain natural events with a seasonal configuration of the sky, they make no deterministic predictions about individual lives; the moral values enshrined in the legends are held to be true for the *whole* tribe.

The most radical difference between the vitalistic beliefs which underlie these myths and the materialistic philosophy of western science concerns the relationship of the observer to the observed. In Newtonian science, the observer is assumed to be independent of, and distinct from, the object observed, which, in turn, is regarded as uninfluenced by the observer. Hence, the relationship between physical objects can be validly expressed in mathematical terms which remain true irrespective of the observer. The Aborigines, on the other hand, did not conceive of themselves as observers separated from an objectified Nature, but rather as an integral part of that Nature. The meaning of the celestial bodies, as of everything else in the environment, was neither self-evident nor independent of the observer; rather it depended on the degree of initiation into tribal lore which elucidated the links between tribal customs and natural phenomena. Without this knowledge the individual was disoriented and powerless in an alien universe.

Astronomy of the Hebrews

Y. Tzvi Langermann

The Hebrew astronomical tradition that shall be surveyed in this essay is that tradition recorded in the Hebrew alphabet dealing with the motions of the heavenly bodies and the structure of the heavens. These writings utilize principally the Hebrew language, but include texts in languages such as Aramaic and Arabic that can be written out in Hebrew script. Topics of specifically Jewish interest, such as calendar computations and doctrinal matters, occupy only a minor portion of this literature. For the most part, the Hebrew astronomical tradition differs little from contemporary writings belonging to the traditions with which Jews found themselves in immediate contact at any given age and place. To the extent that these other traditions may be classified as non-Western, the Hebrew tradition may be by and large considered such.

The earliest substantive materials are found in the Talmud and Midrash. Most of the discussions center upon the structure and physics of the heavens. Of particular interest are several notices of disagreement between Jewish and non-Jewish experts, for example, on the question of whether it is the star itself, or the spherical shell within which the star was thought to be embedded, which moves around the earth.

In other words, we have clear evidence that even at this early date Jewish scholars identified themselves with particular conceptions of the heavens. *Pirquei di-Rebbe Eliezer*, *Baraita di-Mazalot*, and *Baraita di-Shmuel* are three post-Talmudic writings whose precise dating is problematic but which certainly precede the flowering of the sciences under the Abbasids. The latter two are the earliest texts which preserve any mathematical astronomy, e.g., a computational scheme for shadows. In addition, al-Khwārizmī's treatise on the Jewish calendar, which belongs to the Arabic tradition but is almost certainly based on Jewish sources, exhibits positional data for the epoch of the Temple. All of this indicates that a Hebrew tradition, drawing upon Indian, Hellenistic, and other sources, had developed by the eighth century.

Without doubt the years spanning the ninth through sixteenth centuries were the most fecund for the Hebrew tradition. During this period, which is more or less commensurate with what Western historians have long called the medieval age, interest in astronomy was especially stimulated in Arabic speaking lands from Spain to Iraq. Contemporary Jewish writings consist for the most part of exposés or translations of the fruits of Arab science. Dozens of works were written, surviving in hundreds of manuscripts; only a few can be surveyed here. Abraham bar Hiyya created a Hebrew astronomical vocabulary that endured side by side with that developed by the Tibbons, the famous family of translators of Arabic literature. Abraham ibn Ezra's astrological writings were immensely popular both in the Hebrew original and in Latin translation. Both Abrahams utilize more ancient sources that are no longer extant. Isaac Israeli's *Yesod 'Olam* is a thorough analysis of all of the astronomical and historical questions connected with the Jewish calendar; his book, written in 1310 in a polished Hebrew style, may be considered the pinnacle of the Spanish Hebrew tradition. All the same, Hispano-Jewish authors continued to produce treatises in Hebrew and Judeo-Arabic through the end of the fifteenth century. For instance, the work of Abraham Zacuto, so important for the Portuguese

explorers, appeared around the time of the expulsion of Jews from Spain.

Southern France, Italy, and Byzantium were the other major centers of astronomical activity during this period. Emmanuel ben Jacob, Jacob Anatoli, and Mordecai Comtino are, respectively, perhaps the most important representatives of the Hebrew tradition in those lands. In those areas in particular, Jews drew upon Latin, Romance, and other literatures, as well as Arabic materials.

The two outstanding philosophers of this period, ► [Moses Maimonides](#) and Levi Gersonides, participated strongly in the Hebrew astronomical tradition. Maimonides' wrote a small work on the calendar, and he included in his great law code, the *Mishneh Torah*, a detailed scheme for computing the first visibility of the lunar crescent. However, Maimonides' weightiest contribution is the very high value which he placed on the study of astronomy within the context of his religious philosophy, something which encouraged many Jews to acquaint themselves with, at the very least, non-technical resums of astronomical knowledge.

Levi Gersonides was without doubt the most creative representative of the Hebrew tradition, indeed one of the greatest scientists of his epoch. He too developed his astronomical views within the framework of a finely tuned and very comprehensive religious philosophy. Levi was both an observer and a theoretician, and, most notable, one of the rare breed who attempted to fit his own original theory, which had to answer to certain philosophical constraints, to his own observations. Among his other major achievements, Levi invented the Jacob's staff, a simple but accurate instrument for measuring the angular distances between stars; studied the errors involved in instrumental measurements; and arrived at a much greater (and hence more realistic) value for the distances of the stars than those accepted by his contemporaries.

Jews living in Islamic lands, most especially the Yemen, continued to study the ancient and medieval texts well into the twentieth century. In those countries the Hebrew tradition was maintained chiefly through the copying of manuscripts, often transcriptions of Arabic texts into

the Hebrew alphabet. In European countries the study of Latin texts in Hebrew translation seems to have accelerated in the fifteenth and sixteenth centuries. Some three Hebrew translations of Georg Peurbach's *Theorica* were executed, and several Hebrew commentaries were written, *inter alia* by Moses Isserles of Cracow and Moses Almosnino of Salonika, both of whom were leading rabbis of their times.

There is little in the Hebrew tradition that reflects the great advances associated with the European scientific revolution. Joseph Delmedigo, a widely traveled Cretan who studied under Galileo, published the only lengthy and detailed Hebrew exposition of the new science. Other publications, such as Tuviah Cohen's *Maaseh Tuvia* (Tuvia's Opus), present the new science in somewhat abbreviated form; and yet other writings, such as Solomon Maimon's exposé of Newton's work, remain in manuscript. The Hebrew tradition revived during the nineteenth century, particularly due to the efforts of the *maskilim*, advocates for widening the intellectual horizons of Judaism, who published Hebrew scientific texts in a number of fields. With the re-establishment in the State of Israel of a native Hebrew speaking population, and, no less importantly, institutions interested in teaching and writing about astronomy in the Hebrew language, the quantity and scope of the Hebrew tradition have dramatically increased.

Astronomy: Indian Astronomy in China

Yukio Ōhashi

Chinese astronomy and Indian astronomy were originally independent. Both of them already had developed when Indian astronomy was introduced into China along with Buddhism. The exact date of the introduction of Buddhism into China is not known, but it can be said that Buddhism was gradually introduced at the beginning of the Later Han (Eastern Han) dynasty (AD 25–220) or so. According to my study, the earliest information on Indian astronomy reached China at the time of the Later Han.

During the Sanguo (Three Kingdoms) period (AD 220–265), some Buddhist works, where information of Indian astronomy was included, were translated into Chinese. At the time of the Tang dynasty (AD 618–907), some detailed monographs of Indian astronomy and astrology were composed in China. There were some astronomers who were well versed in both Chinese and Indian astronomy. Yixing was one of them.

It is not known whether Chinese astronomy was introduced into pre-modern India or not.

Indian Astronomy in the Later Han Dynasty

At the time of the Former Han (Western Han) dynasty (206 BCE–AD 23), there was no apparent foreign influence on Chinese astronomy. As Buddhism was already known at the time of the Later Han dynasty, there was a possibility that certain aspects of Indian culture, including astronomy, were also introduced into China.

According to my research, some fragments of information about the Indian calendar reached China at the time of the Later Han dynasty (Ōhashi, 1999). There are three reasons for my view:

1. When the Later Han *Sifen* calendar was compiled in AD 85, its first month was proposed to be large, although that was finally rejected. In the Chinese traditional calendar, the first month was small, because the first new moon occurs at the initial point of time, and the second new moon is included in the first day of the next month. To the contrary, the first month of the Indian traditional calendar was large, because the first new moon occurs at the initial point of time, and the second new moon is included in the last day of the same month. I suspect that the rejected proposal of the Later Han *Sifen* calendar might have been influenced by the Indian method.
2. The Later Han *Sifen* calendar has special days called *mori* and *mieri*, which did not exist in the Former Han dynasty. If 1 year is divided into 360 parts and 1 day is included within a part, the day is called *mori*. If the end of a day coincides with the boundaries of the parts, the day is called *mieri*. These days are of no use in Chinese traditional calendars, but they are similar to certain concepts of Indian traditional calendars, such as the method of intercalation in the *Arthaśāstra* (see the section on Yixing below; for details, see Ōhashi, 2001).
3. In Chinese traditional calendars, midnight is considered the beginning of a day. However, when the date of the half moon and full moon was calculated in the Later Han *Sifen* calendar, daybreak was considered to be the beginning of a day. In Indian traditional calendars,

sunrise is usually the beginning of a day. Therefore, the Chinese use of daybreak might have a connection with the Indian method.

From these three reasons, I suspect that certain information about the Indian calendar reached China. However, the information must have been fragmental, and did not influence the Chinese calendar very much.

Indian Astronomy in Chinese Buddhist Texts

The *Madengqie-jing*

At the time of the Sanguo (Three Kingdoms) period (mid-third century AD), a Buddhist text called *Śārdūlakarṇa-avadāna* in Sanskrit was translated into Chinese by Zhu Lüyan and Zhi Qian as the *Madengqie-jing*. This is the first Chinese text where Indian astronomy and astrology are explicitly mentioned. This text explains lunar mansions and the astrology based on them at length and also mentions some calendrical information.

The astronomical system of the *Śārdūlakarṇa-avadāna* is similar to *Vedāṅga* astronomy, which is one of the six branches of auxiliary learning for the *Veda*. According to my research, *Vedāṅga* astronomy was produced in North India sometime between the sixth and the fourth centuries BCE (Ōhashi, 1993). The description of astrology in the *Śārdūlakarṇa-avadāna* is also based on the Indian traditional system.

The original Sanskrit version of the *Śārdūlakarṇa-avadāna* has a description of the annual variation of the gnomon shadow, which is similar to that in *Vedāṅga* astronomy. The Chinese version, *Madengqie-jing*, also has a description of the annual variation of the gnomon shadow, but it is different from the Sanskrit original. Shinzō Shinjō, a pioneer of the study of the history of Eastern astronomy, pointed out that the description of the *Madengqie-jing* is based on the data around 43°N, and that the data might have been incorporated in Central Asia (Shinjō, 1928: pp., 217–218).

The *Śārdūlakarṇa-avadāna* was also translated into Chinese as the *Shetoujian-taizi ershiba-xiu jing* by Zhu Fahu at the time of Xi-Jin (Western Jin) dynasty (AD 265–316).

The *Daji-jing*

The *Daji-jing* (or *Dafangdeng-dajijing*) is a collection of *Mahāyāna* texts in Chinese. The *Yuecang-fen* (one text in the *Daji-jing*), which was translated by Narendrayaśa in AD 566, is the earliest Chinese text where zodiacal signs are mentioned.

The *Ricang-fen* (another text in the *Daji-jing*), which was translated by Narendrayaśa in AD 586, also mentions zodiacal signs. It is interesting to note that the annual variation of the length of daytime and that of the gnomon shadow, which are similar to those of the *Vedāṅga* astronomy, are mentioned there, but the position of the sun corresponding to their data is given with reference to zodiacal signs. This means that the system of *Vedāṅga* astronomy was still in use when Greek horoscopy reached India. *Vedāṅga* astronomy was widely used in India from sometime between the sixth and the fourth centuries BCE to sometime during the second and fourth centuries AD, and was mixed with the system of zodiacal signs which was introduced into India along with Greek horoscopy in the second or third century AD (Ōhashi, 2002).

The *Ricang-fen* of the *Daji-jing* is, therefore, an important source for studying the history of Indian astronomy. It says that the length of daytime and nighttime is 15 *shi* (which corresponds to Indian *muhūrta* or 1/30 of a day) in the months of Scorpio and Taurus, and that daytime is 12 *shi* (minimum) and nighttime is 18 *shi* (maximum) in the month of Aquarius, and daytime is 18 *shi* and nighttime is 12 *shi* in the month of Leo. The length of daytime and nighttime changes linearly. The above-mentioned data look strange at first sight. The relationship between the length of daytime and nighttime and the sign of zodiac differs by one. For example, the above data tell that the vernal equinox occurs in the month of Taurus, and not in the month of Aries. The only possible explanation of this difference is that the data of the length of daytime and nighttime is for the

beginning of the month, and the sign of the zodiac is for the end of the month. The linear function of the length of daytime and nighttime is the same in *Vedāṅga* astronomy. My studies reveal that this function is not the result of interpolation from the observational data around the solstices, but the result of extrapolation from the observational data around the equinoxes in North India. The *Ricang-fen* also gives the length of the midday gnomon shadow, which is basically the same as in *Vedāṅga* astronomy, which is also based on observational data from North India. Here, we can see that *Vedāṅga* astronomy was still widely used even after Greek horoscopy was introduced into India (Ōhashi 2002).

Indian Astronomy During the Tang Dynasty

The *Jiuzhi-li*

One system of Hindu Classical Astronomy was introduced into China. It was recorded in Chinese as the *Jiuzhi-li* (AD 718) of Qutan Xida, which is included in his (*Da-*)*Tang Kaiyuan-zhanjing*. The author, Qutan Xida (probably a Chinese transliteration of his Indian name Gotama Siddha), belonged to a family of Indian astronomers in China and was the director of the national observatory. In the title *Jiuzhi-li*, *jiuzhi* corresponds to the Sanskrit word *navagraha* ["nine planets", i.e. sun (Ravi or Sūrya), moon (Candra), five planets – Mars (Maṅgala), Mercury (Budha), Jupiter (Bṛhaspati or Guru), Venus (Śukra) and Saturn (Śani), Rāhu (ascending node of the lunar orbit) and Ketu (usually considered to be the descending node of the lunar orbit)]; *li* means calendar. This work explains the method for calculating the sun's longitude, the moon's longitude, and solar and lunar eclipses, etc. This text also contains a sine table. The work also says that Indian numerals are mentioned, but the actual shape of the figure has not come down in extant texts.

Kiyosi Yabuuti pointed out that some astronomical constants of the *Jiuzhi-li* are similar to the *Sūryasiddhānta*, which was summarized in the *Pañcasiddhāntikā* of Varāhamihira (sixth century AD). This is a text of the *Ārdharātri*

school of Classical Hindu Astronomy (Yabuuti, 1944/1989, 1979; also see Yano, 1979).

It is interesting to note that the traditional calendars of mainland Southeast Asia (except for Vietnam) and also the classical astronomy of Tibet are related to the *Ārdharātri* school. It may be that the *Ārdharātri* school was quite popular among Buddhists. The *Jiuzhi-li* has never been used as an official calendar in China, because the tradition of Chinese original astronomy was so strong.

Yixing

There was also a famous monk, astronomer Yixing (AD 683–727), who knew about Indian astronomy. For example, he mentioned the Indian zodiac in his *Dayan* calendar. However, he made his *Dayan* calendar in a Chinese traditional way. There is only one thing which I suspect shows Indian influence in his *Dayan* calendar. It is the change of the meaning of *mieri*.

Yixing explained the method to calculate the *mieri* as follows:

If the *xiaoyu* (time in terms of 1/3,040 day) of the mean new moon is less than *shuoxufen* (=1,427), subtract the *xiaoyu* from the *tongfa* (=3,040), and multiply the result by 30, and subtract the result from *miefu* (=91,200). Divide the result by *shuoxufen*. The result is the number of days. Count the days from the mean new moon day and take the day after the resultant day. It is the *mieri*.

The meaning of this *mieri* is as follows. Let a synodic month be divided into 30 parts. Then, sometimes a part is included within a day. This kind of day is the *mieri* defined by Yixing. This *mieri* is similar to the "omitted *tithi*" in Indian calendars. In *Vedāṅga* astronomy, a *tithi* was a 1/30 part of a synodic month, where the equation of centre was not known. In Hindu Classical Astronomy, a *tithi* is a period of time during which the longitudinal difference of the sun and moon changes by 12°. If a *tithi* is included within a day, the *tithi* is called "omitted *tithi*". In Hindu traditional calendars, the name of a civil day is determined by the number of *tithi* at the beginning (sunrise) of the day. Therefore, the number of an omitted *tithi*, which does not include any sunrise, actually disappears from the calendar.

The significance of Yixing's definition is that when the sum of the *mori* (a day which is included within a segment of 1/360 of a tropical year) and *mieri* grows to 30, one intercalary

month is produced. This way of thinking is similar to certain descriptions in Indian classics, such as the *Arthaśāstra*. A similar description is also found in a Chinese version of the Buddhist text *Lishi-apitan-lun*, translated by Zhendi at the middle of the sixth century AD.

I suspect that Yixing knew this Indian method, and changed the meaning of the *mieri* in order to make it meaningful in Indian calendrical context (Ōhashi, 2001).

Other Texts in the Tang Dynasty

In addition to the above-mentioned texts, the *Suyao-jing* is also famous. In the title, *su* means lunar mansions, *yao* means planets and *jing* means canonical scripture. It is an astrological work which was compiled by Amoghavajra in the middle of the eighth century AD. It is based on Indian horoscopic astrology.

There is also an astrological work with planetary ephemerides entitled *Qiyao-rangzaijue*, compiled by Jin Juzha, who is said to have been a Brahman priest from Western India, in the early ninth century or so. In the title, *qiyao* means seven planets, and *rangzaijue* means formulae to avoid disasters (caused by planets). This work is a kind of mixture of Indian astrology and Chinese astronomy. It includes the ephemerides of the five planets, Rāhu, Ketu and the sun. In Indian astronomy, Ketu usually means the descending node, or comets. However, Ketu in the *Qiyao-rangzaijue* is, according to Michio Yano's study, the apogee of the lunar orbit. This is a special feature of this work (Yano, 1986).

We have seen some records of Indian astronomy in Chinese sources. We have to keep in mind that Indian influence on Chinese astronomy was very small. The tradition of Chinese original astronomy was very strong, and it seldom accepted foreign influence. However, we can find some exceptional influences in Chinese sources, and these exceptions draw attention to researchers.

Atomism in Islamic Thought

Alnoor Dhanani

Atomism, the view that there are discrete irreducible elements of finite spatial or temporal space, played a significant role in Islamic intellectual history. It was upheld by most practitioners of the uniquely Islamic discipline of *kalām*. However, some practitioners of *kalām* (i.e., *mutakallimūn*) as well as all but one of the practitioners of *falsafa* (i.e., *falāsifa* – those engaged in the Neoplatonized Peripatetic philosophy of medieval Islam) were antiatomists. There was thus a lively debate between atomists and antiatomists, regarding not only matter theory,

but also other areas of natural philosophy and cosmology, particularly theories of space, time, void, motion, and causality.

Kalām has no counterpart in the Western tradition. Even though primarily theological in orientation, it is not equivalent to theology. The subject matter of *kalām* includes not only theological topics, e.g., the nature and attributes of God, prophecy, and revelation, but also philosophical problems of cosmology, logic, anthropology, psychology, etc. The origins of *kalām* are obscure and a subject of debate. Suffice it to say that *kalām* arose in the mid-eighth century, and that during the later half of that century, questions about the nature and attributes of objects were being discussed. In their discussion of such questions among themselves and with others from the various religious and intellectual traditions of the Hellenized Near East, the *mutakallimūn* had access to views and theories propounded by the intellectual, doctrinal, and sectarian movements of Late Antiquity: Neoplatonism, Stoicism, Manicheanism, Dualism, Bārdaišānism, etc. Little is known about the *mutakallimūn*'s manner of access to these views. It was probably oral and through personal contact. Such a transmission is in sharp contrast with the large-scale translation of Greek philosophical and scientific texts during the late eighth and ninth centuries which gave rise to *falsafa*.

The *mutakallimūn* of the late eighth century held three theories of matter and its attributes. In the first, bodies are the only constituents of the world. All secondary qualities like sound, taste, color, etc. are thus corporeal. It follows that perceptible objects consist of several interpenetrating bodies. This view, whose origins are Stoic, was held by some Dualists. Its early *kalām* subscribers were ḥishām ibn al-ḥakam (d. ca. 795), and al-Aṣamm (d. 815). Later, the antiatomist Ibrāhīm ibn Sayyār al-NaẒẒām (d. 835–845) advocated it, albeit holding that motion was the sole accident.

In the second theory, unextended accidents are the only constituents of the world. Extended bodies result from a combination of accidents, namely, color, taste, hot/cold, rough/smooth. The origins of this view lie in Neoplatonism and

Christian theology. Its *kalām* subscribers were ḍirār ibn 'Amr (d. 815), ḥaḥṣ al-Fard (fl. 810), and ḥusayn al-Najjār (d. ca. 835–845).

The third theory holds that accidents and bodies constitute the world, and that bodies are constituted from atoms. This view had its partisans among the Dualists and the Bārdaišānites. It was appropriated into *kalām* by Abū al-Hudhayl al-'Allāf (d. 841) of the Basrian Mu'tazilī school of *kalām*; the Baghdadī Mu'tazilī Bishr ibn al-Mu'tamir (d. 825–840); and Mu'ammār al-'Abbād al-Sulamī (d. 830). Towards the mid-ninth century, the atomic theory displaced its rivals to become the dominant physical theory of *kalām*. Atomism was upheld by the Ash'arī *kalām* school formed in the tenth century in opposition to Mu'tazilīs, particularly regarding questions of man's free will and God's absolute power. However, atomism was attacked by the *falāsifa* who upheld Aristotelian arguments. In the eleventh century, the Basrian Mu'tazilī Abū al-ḥusayn al-Baṣrī (d. 1044) embraced *falsafa* physical theory and abandoned atomism. Atomism declined further in the twelfth and later centuries with the growing influence of Ibn Sīnā's (d. 1037) philosophy. Even though atomism was never actually abandoned, it was no longer central to post-twelfth century *kalām*.

As none of the writings on physical theory of the eighth and ninth century *mutakallimūn* has survived, their theories must be reconstructed from extant fragments. The principal source has been the doxography, *Maqālāt al-islāmīyīn* (The Doctrines of Muslims) by the former Mu'tazilī and founder of Ash'arī *kalām*, Abū al-ḥasan al-Ash'arī (d. 935). The following account of early atomism may be drawn: early *kalām* atomists distinguished between the atom (denoted by *jawhar* (atom), *juz'* (part), *al-juz'alladhī lā yatajazza'* (the indivisible part)) and the body. The body has length, breadth, and depth, while the atom lacks these dimensions (however al-ṣāliḥī [fl. end of ninth/early tenth century] held that the atom was a body). Rather, they believed that dimensions are produced by combinations of atoms. Hence, a minimal length arises when two atoms combine (or, in the formulation of the *mutakallimūn*, a line is formed by

the combination of two atoms). There were different views on the minimal number of atoms which constitute a body having length, breadth, and depth: Abū al-Hudhayl held that it was six; Mu‘ammar held that eight were required; and Abū al-Qāsim al-Balkhī (d. 931) held that four sufficed.

There are obvious parallels between *kalām* and Greek atomism regarding proofs for the existence of atoms, as well as terms which denote the atom. Yet the concept of dimensionless atoms combining to form bodies with dimension is unique to *kalām*. New light has been shed on this puzzling view, and on *kalām* physical theory in general, by the rediscovery of eleventh century sources. Of particular importance are the Basrian Mu‘tazilī texts of Ibn Mattawayh and Abū Rashīd al-Nīsābūrī (both fl. first half of eleventh century), as well as Ash‘arī texts by Abū al-Ma‘ālī al-Juwaynī (d. 1085) and Ibn Fūrak (d. 1015). These sources reveal that, in his reformulation of *kalām*, the Basrian Mu‘tazilī Abū Hāshim al-Jubbā‘ī (d. 933) had redefined the atom as “that which occupies space (*mutaḥayyiz*),” a designation which was also applied to the body. From this designation, as well as arguments advanced in support of the theses that the atom has magnitude (*miṣāḥa*) and its shape resembles a cube, it is clear that the atom must somehow be extended (the Ash‘arī *mutakallim* Abū Bakr al-Fūrakī (d. 1085) states: the atom is the smallest of what is small with respect to volume). Paradoxically, these *mutakallimūn* insisted that despite its magnitude the atom lacked length, breadth, and depth. Like their earlier colleagues, they continued to hold that dimensions were produced by combinations of atoms. Moreover, they considered any difference between their view of the atom and the earlier view as marginal; it was partially conceptual but partially a result of the manner of expression.

These texts suggest the interpretation that a geometry of discrete space underlies *kalām* atomism (as in Epicurean atomism). In ancient and medieval thought, any distinction between geometrical and physical space was inconceivable. If physical space was continuous, then so was geometrical space. Likewise, discrete physical

space meant discrete geometrical space. Hence, *kalām* formulations of “indivisible,” “dimension,” “magnitude,” and “body” need to be analyzed within discrete geometry. Here, a point, which is defined as that which has no parts, is equivalent to the indivisible magnitude (i.e., atom). Next, a line, which is terminated by two end points, must consist of at least two indivisibles. It follows that two indivisibles constitute the least line and are the least to constitute the dimension of length. The *kalām* atom cannot, thus, have length, breadth, or depth, but it has magnitude for it is an indivisible of discrete (and not continuous) geometry. The combination of atoms to form linear dimensions is no longer problematical; unlike points of continuous geometry which lack both dimension and magnitude, atoms/indivisibles of discrete geometry have minimal magnitude yet lack dimension. Such atoms combine to form objects with larger magnitudes and dimension. In a discrete geometry whose indivisibles are square-shaped (as seen from a continuous geometry, for the *mutakallimūn* state that the atom *resembles* a square; having no dimensions it cannot be a square!), one may configure minimal bodies from four, six, or eight atoms.

In his critique of atomism, Aristotle argued that atomism entails indivisible parts of space, time, and motion. Accordingly, most eighth and ninth century atomist *mutakallimūn*, and many later *mutakallimūn* upheld the minimal parts of space, time, and motion. In the tenth century, Abū Hāshim al-Jubbā‘ī abandoned the minimal parts of space (and consequently minimal parts of time and motion) in response to difficulties raised by antiatomists. His successors did not all adopt this view; some continued to say that space, time, motion, and matter were constituted out of indivisibles. We may also note that the atomist *mutakallimūn* upheld the existence of void spaces.

Atomism posed several conceptual and geometrical difficulties, some of which are traceable to Aristotelian arguments against atomism. It may be relevant to mention some Islamic contributions. One argument formulated by Abū al-Hudhayl, which is based on Zeno’s dichotomy

paradox, was the ant and sandal argument. Imagine an ant creeping over a sandal. In order to traverse the sandal, the ant must first traverse half the sandal; but to traverse half, the ant must first traverse half of this, and so on. Hence the traversal cannot commence unless the division terminates at an indivisible (i.e., atom). Abū al-Hudhayl's student, the antiatomist al-Naẓẓām, responded with his theory of leap (*tafra*), saying the ant does not traverse through all points on the path of traversal, but it traverses through some and leaps over others. Hence, al-Naẓẓām claimed, one may traverse from one location to another without traversing all intervening points. The theory of leaps played an important role in discussions of physical theory, if only to illustrate the absurdity of the actually infinite division of matter which was attributed to al-Naẓẓām. Al-Naẓẓām also formulated a clever argument against atomism. Imagine a rotating millstone. Since both an inner circle and the millstone's circumference must complete a rotation in equal time, when an inner circle is ten atoms in length, and the circumference is a hundred atoms, for each unit of space traversed by an atom on the inner circle, an atom on the circumference would have to traverse ten units. Explaining this, al-Naẓẓām resorted to his theory of leaps: when an atom on the inner circle moves one unit, an atom on the circumference moves one unit and leaps nine units. Abū al-Hudhayl, however, responded that the atom on the inner circle moves for one time unit and rests for nine units, while the atom on the circumference moves for all ten units. Al-Naẓẓām objected that this entails that particles of a solid body cannot adhere to each other but must be set loose to allow for such moments of motion and rest. Hence, a rotating solid body must disintegrate (*tafakkuk*) and its internal configuration of atoms be modified. The atomist *mutakallimūn*, unable to answer al-Naẓẓām's challenge, accepted the internal disintegration of a rotating body. However, they considered it to be analogous to a salt shaker where salt particles move freely within the confines of the shaker.

Why did the *mutakallimūn* embrace atomism? This question has puzzled researchers,

particularly given the difficulties atomism raised. The thesis that atomism was theologically more acceptable than the continuously divisible matter theory of the *falāsifa* has been widely accepted. Continuous divisibility raises problems of infinity, and the *mutakallimūn* were mindful of the relationship between ending infinite regress in the argument for the temporal creation of the world and the argument for the divisibility of matter. Yet the question still remains as to why three theories of matter were considered theologically sound in early kalām, and why early atomists did not claim that their theory was, theologically, the most sound. The assertion that antiatomists were heretics is only found after the tenth century when atomism had triumphed. The question of the affinity of atomism to occasionalism has also been raised, but this needs to be reexamined in the light of new sources.

Atomism was also upheld by the famous physician and *faylasūf* Abū Bakr Muḥammad ibn Zakariyā' ► *al-Rāzī* (d. 925). However, surviving accounts are scanty. We only know that his atoms were extended (like Democritus' atoms). Atomism is part of al-Rāzī's cosmology of the five eternal: God, Soul, Space, Time, and Matter upheld by the ṣābiāns of ḥarrān. Some of al-Rāzī's views may derive from Irānshahrī (fl. late ninth century) about whom very little is known.

Ātreya

Guy Mazars

Ātreya or Punarvasu Ātreya was probably the physician of an ancient king of Gāndhāra. The name Ātreya implies that he was either a descendant or a disciple of Atri, a sage mentioned in the *Veda*. The date of Ātreya may be fixed before the grammarian ► [Pāṇini](#) (seventh century BCE) and after the *Atharvaveda* (1200 BCE), ca. 1000 BCE.

On the basis of his teachings, six of his disciples composed medical treatises. One of them, Agniveśa, wrote the *Agniveśatantra* or ‘System of Agniveśa’, which became known as the *Carakasamhitā* after its revision by ► [Caraka](#). Another disciple, Bhela, wrote the *Bhelasamhitā*, which has fragmentarily been preserved in a single manuscript. Unfortunately, the text is mutilated and full of scribe’s errors. Some scholars are of the opinion that the *Bhelasamhitā* may be older than the *Carakasamhitā*. The *Hārītasamhitā* is ascribed to a third disciple, also called *Ātreyasamhitā*. But the text that has come down to us is regarded as a relatively late work of an apocryphal nature, though parts of it might be old.

As to the treatises composed by the other three disciples of Ātreya, they have not been preserved. But quotations from their works occur in many commentaries. Two other Ātreya, Kṛṣṇātreya and Bhikṣu Ātreya, are mentioned in the *Carakasamhitā*. According to the *Mahābhārata*, the ‘Great Epic of India’, Kṛṣṇātreya was the founder of a medical school. There is mention of another Ātreya connected with the Buddhist University of Takṣaśilā. He was the teacher of a contemporary of Buddha (fifth century BCE), the famous surgeon Jīvaka to whom tradition attributes extraordinary operations.

Aztec Science

Frances Berdan
California State University San Bernardino,
San Bernardino, CA, USA

The name Aztec most commonly refers to Nahuatl-speaking people who dominated the Basin of Mexico, and indeed much of central and southern Mexico, in the fifteenth and early sixteenth centuries. The most prominent of these people called themselves Mexica. They settled their island city of Tenochtitlan (today Mexico City) in AD 1325, in the midst of a large number

of well-established cities. The Mexica, as hunter and gatherer immigrants from the northern Mexican deserts, were latecomers to the Basin of Mexico and combined their nomadic-style culture with the ways of life of long-settled villagers and urban dwellers. In the fifteenth and early sixteenth centuries, numerous different ethnic groups coexisted in the Basin of Mexico; these groups were politically organized in city-states and exhibited visible emblems of their specific cultural identities (such as patron gods, clothing styles, and distinctive languages and dialects). Three of these groups, the Mexica of Tenochtitlan, the Acolhua of Texcoco, and the Tepaneca of Tlacopan, joined in a military alliance in AD 1430, creating the Aztec empire which subsequently conquered much of Mexico. The empire was short-lived; Tenochtitlan was conquered in AD 1521 by Spanish forces.

The Mexica were the last of a long succession of complex states and civilizations in pre-Hispanic central Mexico. As such, they inherited many cultural traditions from prior civilizations, including much in the scientific realm. The Mexica were devout admirers of their predecessors, the Toltecs (ca. AD 950–1150), to whom they attributed much of their scientific knowledge. This included medicine, geology and mining, astronomy and calendrics, architecture, and fine technical arts (especially feather-working, metal-working, and stone-working). While the Mexica honored the Toltecs with these inventions, most of these skills and surely much of this knowledge clearly predated the rise of the Toltec civilization in central Mexico.

Mexica society was hierarchical and highly specialized. In general, pronounced distinctions between nobles and commoners, between different occupational specialists, and between members of different ethnic groups also meant differences in access to certain scientific knowledge and specialized training. Noble boys were educated in priestly schools where the curriculum included literacy skills, astronomically based calendrics, and the learning of histories, orations, and songs. Some highly placed individuals actively pursued scientific knowledge and were renowned as great thinkers or philosophers.

Medicinal knowledge and skills were in the hands of highly trained physicians, who appear in the documents as men or women skilled in herbal remedies and treatments of injuries and afflictions. Midwives also applied their extensive medical knowledge to the curing enterprise. Specific forms of scientific knowledge, embedded in industrial arts such as stone- or feather-working, were typically the province of exclusive occupational (and sometimes ethnic) groups, who passed on their craft from parent to child. Engineering and architecture (manifest, for instance, in the construction of buildings, dikes, and elaborate irrigation works) would have required special training, perhaps in an apprentice-style setting. Unfortunately, the documents are silent on this. Much knowledge of agronomics, as in genetic engineering of food crops, was probably developed by farmers themselves, who slowly but persistently developed increasingly productive strains of maize and other crops. While documentary evidence is uneven and inconclusive, it appears that some scientific knowledge was developed and passed on in a formal, literary context while other knowledge (such as seed selection and midwifery) was maintained in a more informal folk realm.

Mexica scientific understandings were empirically based, but also closely linked to religious beliefs. To the Mexica and their neighbors, the natural and supernatural worlds shaded into one another, and their practical scientific inquiries cannot be understood apart from their religious concepts and abstract symbolism. So, for example, empirical astronomy was intertwined with astrology and predictions of human fates. The involved system of calendrics was largely based on prolonged astronomical observations, but the calendars themselves were applied to godly demands and ritual as well as practical ends. Medicine combined pragmatic remedies with shamanism, divination, and magical cures. Glyphic writing, sculpture, architecture, and the luxury crafts of stone-, feather-, and metal-working all relied on sophisticated and well-honed practical technologies; the resulting works served secular goals and/or displayed essentials of Aztec religious symbolism. Animals

and plants resided in the everyday, visible natural world, but also carried a heavy load of abstract meaning in the less tangible world of mythology and cosmic forces. To the Mexica and their neighbors, then, an empirical, scientific realm of understanding and inquiry was intricately intertwined with a more abstract, religious realm.

Mexica scientific concepts and knowledge are understood only imperfectly today, mainly due to the paucity of primary source materials on the subject. The ancient peoples of central Mexico, including the Mexica, maintained extensive libraries of pictorial books (codices), but almost all of these were destroyed during or shortly after the Spanish conquest in 1521. An Aztec exception is the *Matrícula de Tributos* (1980) which contains numerous illustrations of plants and animals embedded in place name glyphs, as well as indications of geographical sources of certain raw materials (such as jaguar pelts, precious stones, gold, woods, birds, and feathers). Some of the information contained in pre-Columbian books (such as the *Matrícula* and others now lost) was reproduced or reconstructed following the Spanish conquest and set down in written and/or pictorial form, usually under the supervision of Spanish friars. The most famous of these, and one which includes considerable textual and pictorial information on astronomical knowledge, natural history, and medicinal practices, is *Historia general de las cosas de Nueva España* [General History of the Things of New Spain (Florentine Codex)]. This compendium relied on native informants and was compiled in the Nahuatl (Aztec) language by the Franciscan friar Bernardino de Sahagún (1950–1982).

Additional early colonial codices contain interesting scientific details, such as the images of plants and animals in place name glyphs and a star-gazing priest in the Codex Mendoza (Berdan & Anawalt, 1992) or the several herbal remedies pictured and described in the Cruz-Badiano herbal (Bye & Linares, 2013). Also available, and providing variable enlightenment on native scientific concepts, are Spanish-language histories and descriptions of the Mexica and their neighbors by Spanish secular and

religious officials. Among the most revealing of these are the natural histories of Francisco Hernández (1959) and Gonzalo Fernández de Oviedo y Valdés (1959), although the latter focuses primarily on areas to the south and east of the Aztec imperial domain. These postconquest sources blend native concepts and information with European understandings and conventions and must be read in that light.

Written sources are augmented by the material remains of the people themselves, discovered and interpreted archaeologically. The remains of structures provide clues to architectural and engineering skills; urban layouts suggest detailed understandings of the movements of celestial bodies; artifacts in metal, stone, and feathers (and the tools that produced them) reveal sophisticated industrial technologies; and ancient food remnants, such as corncobs, demonstrate a steady enhancement of crop productivity through hybridization and selective breeding. In addition, human physical remains have left clues to Aztec health, nutrition, and medical practices.

A closer look at astronomy, natural history, and medicine is presented below to illustrate the nature, extent, and goals of Mexica scientific inquiry.

Cosmology, Astronomy, and Astrology

Like their forebears and contemporary neighbors, the Mexica were sophisticated observers of astronomical phenomena. Systematic celestial observations and studies were reportedly the domain of the elite. Imperial rulers such as Motecuhzoma Xocoyotzin (r. Tenochtitlan 1502–1520) had duties which included observing star groups in the night sky, as well as carefully following the morning star, Venus. Nezahualpilli, early sixteenth-century ruler of neighboring Texcoco, spent endless nocturnal hours observing and recording the movements of celestial bodies from the roof of his royal palace. This “observatory” was structured so a man could lie down and contemplate the night sky through small perforations through which were placed lances with

cotton spheres atop. While this description of observing techniques is vague and not entirely clear, it does indicate that careful, rigorous, naked-eye techniques were employed to follow changes in the celestial realm.

Although rulers may have spent some of their nighttime hours studying the heavens, this activity was more commonly performed by priests, who spent many waking hours at night. The *Codex Mendoza* shows one such priest engaged in observing the heavens for the purpose of marking the passage of time. Some temples may have served as “sighting stations” or observatories, from which pairs of crossed sticks were aligned to gain accurate lines-of-sight to celestial phenomena. Lines-of-sight were also established between temples and recognizable points on the horizon and between specific urban structures. The passage of the sun through the seasons could be readily charted in this fashion, with solstices and equinoxes especially marked. For instance, in Tenochtitlan the spring equinox was marked by the passage of the sun directly through an opening between the twin shrines of the Great Temple. This was extremely important to the Mexica; reportedly the emperor Motecuhzoma, micro-managing new construction of the temple, ordered imprecise work torn down and rebuilt to assure the temple conformed to its spring equinox alignment (Motolinia, 1971). This emphasis on precision, along with the various observational devices and techniques, also allowed the ancient Mexicans to track the phases of the moon, record the arrangements of star groups (constellations), follow the movements of the Pleiades, calculate the revolution of Venus, and predict eclipses. They also attended to other celestial phenomena such as meteor showers and comets. Their eyes and minds were glued to the heavens (Aveni, 2001, 2012).

The movements of the sun, stars, moon, and planets had important practical and ritual applications for the Mexica and their neighbors. They were especially concerned with the passage of time and developed complex and accurate calendars of 365 and 260 days. The former was a solar calendar especially used in seasonal agricultural

and state-ceremonial planning; the latter, approximating periods of human gestation and the agricultural cycle, was the basis for divination and astrological determinations. Combined, these two calendars yielded a 52-year cycle which carried a heavy load of complex symbolism and obligatory rituals. To the Mexica, time was cyclical and repetitive, and much as the individual seasons and years came and went with marked similarity, so also did the 52-year “centuries.” The fate-oriented Mexica also saw cycles in the creation and destruction of the universe. Legends told of four prior worlds and their destructions, with the Mexica living in the “fifth sun.” A great deal of carefully prescribed ritual and human sacrifice was required of the central Mexicans to assure the maintenance of this world, whose continuance was especially vulnerable at the closing of each 52-year unit. Thus, a great deal of cultural interpretation was lent to the systematic visual astronomical observations of priests and rulers.

The Mexica conception of the universe and its heavenly bodies was a combination of scientific observations and ideological constructs. Celestial and terrestrial space was united in a hierarchical scheme containing thirteen heavenly layers and nine layers of the underworld. Heavens and underworld were linked by the earth’s surface, which was counted in each. The world above the earth combined visible phenomena with invisible gods and goddesses; for instance, the moon occupied the layer above the earth, followed by the clouds in the next tier, then the sun, Venus, and the Fire Sticks constellation (possibly the belt and sword of Orion) in successive levels. It should be kept in mind that certain celestial bodies, especially the sun, moon, and Venus, were not only visible phenomena but were also accorded divine status. Heavenly layers contained invisible deities, with the male/female creator god at the apex. This whole, integrated arrangement is quite different from the heliocentric (sun-centered) and geocentric (earth-centered) concepts developed in the Eastern Hemisphere.

The linking of heavens and earth is manifest in much of central Mexico’s urban planning. Some scholarly arguments favor the position that cities

and temples conform to astronomically significant alignments. The orientation of Teotihuacan (ca. AD 1–650/750), for instance, may have been associated with the movements of the Pleiades (Aveni, 2012), and we have already seen the spring equinox orientation of Tenochtitlan's Great Temple. At least some astronomically based alignments directed city planning, although its extent is currently debated (see Smith, 2008). In those cases where the ancient Mexicans oriented their centers and temples along astronomically meaningful lines, the human, sacred, and scientific were meshed into a single cultural realm.

Natural History and Ecology

Like the celestial bodies above the earth, the natural phenomena on and in the earth were viewed both scientifically and symbolically. In this close perceived link between natural and supernatural, the creatures of the earth performed a variety of functions in both visible and invisible cultural realms. Birds and beasts were valued as providers of food, fur, and feathers, but were also frequent subjects of metaphors and players in myths and legends. The concrete and abstract were linked: the roles that creatures played in myths, the meanings they carried in the ritual calendar, and the messages they conveyed in metaphors were based on empirical observations of behavior, life cycles, and anatomy (see Berdan, 2014). For example, a human fugitive was likened to a fleet deer, the patting of tortillas compared to the flapping wings of a butterfly, and an eavesdropper described as the little mouse that inhabited every nook and cranny of a house. Close, systematic observations also led to an understanding of the transformations of the hummingbird, which seemingly died during nighttime or winter months and came to life in the warmth of day or springtime. Not surprisingly, hummingbirds were associated with human life-death transformations.

Much of the study of wild creatures undoubtedly took place in the animals' natural habitat, so that, for instance, the wily hunting techniques of

the bobcat, the reproduction of locusts underground, and the nesting of certain birds in "inaccessible places" are recorded. However, the Mexica also maintained a large zoo and aviary in the city of Tenochtitlan, and such a setting would have provided ample opportunity for some degree of observation and study. This was particularly significant for understanding birds and beasts from distant parts of the empire; these were especially valued for their fine feathers or precious pelts.

Habitats of various creatures were meticulously recorded, surely from direct attention to nature: the gray fox was a cave dweller, the tadpole lived in freshwater among algae and water lilies, the raccoon preferred forests and crags, and so on. The many parts of nature were perceived as interconnected: the American Bittern's enthusiastic nighttime singing predicted heavy rains and abundant lacustrine fish; the Ruddy Duck's evening antics signaled rain at dawn; the song of yet another bird heralded the onset of frost.

The Mexica readily understood relationships among the various creatures themselves, including humans. Human involvement in ecological dynamics at times had significant consequences. The Mexica were aware of the rarity of certain creatures, such as the wood ibis or certain serpents; indeed, they considered it a bad omen to catch the wood ibis, a cultural constraint which would have served to preserve this rare avian. In another example, the Mexica king Ahuitzotl (r. 1486–1502) was reportedly responsible for bringing great-tailed grackles to Tenochtitlan from eastern lands and ordering their protection. Unexpectedly, these birds thrived to such an extent that they became an ecological burden, understandably losing their popularity. In these examples, the Mexica were active participants in a continuous ecological drama, engineering changes with often-unanticipated consequences.

Medicine and Health

The Mexica were scientific and empirical in their discovery and use of medical cures for a large

number of illnesses and injuries. The specialized doctor, or *ticitl*, used practical approaches to his/her profession, examining and diagnosing physical problems and prescribing appropriate cures. Physicians could call upon a large pharmacopoeia derived from herbs, roots, animals, and minerals to relieve symptoms, heal injuries, and restore health. They were skilled in soothing burns, setting broken bones, and suturing lacerations, many of these latter injuries undoubtedly suffered in the frequent battles fought in this militaristic society. Midwives also entered the curative arena, being skilled in herbal remedies as well as childbirth processes.

Medical procedures could be multi-staged and quite complicated. Broken bones, for instance, were first set and then splinted with poultices of specified ground roots or herbs. There was some variety in these usages, as the curative ground roots or herbs could be spread on the injury, drunk with pulque, or enjoyed in a bath. A bitten tongue was first subjected to a mixture of chili cooked with salt, followed by a more comforting application of bee or maguey honey. The Mexica considered at least 132 herbs to have curative properties, and these were applied to at least 40 ailments other than injuries. Curable ailments included nosebleed, pimples, headache, diarrhea, fatigue, coughs, chest pains, nausea, difficult childbirth, and many fevers and infections. Other medical issues (some more serious than others) included compromised mental states, arthritis, tuberculosis, insomnia, and hair loss. Some individual infirmities could be served by a variety of cures – for instance, 45 different herbs could be used to relieve fevers and 18 could be applied to festering skin. On the other hand, some remedies had multiple uses – one herb, for instance, could reportedly slow bleeding, inhibit vomiting, relieve side and chest pains, and in general restore a person's strength. The effectiveness of some of these natural remedies has been verified scientifically. In one study, of 118 plants used by the Mexica for curing, 85 % were shown to contain medicinal components recognized in the twentieth century (Bye & Linares, 1999, p. 5). For instance, the Mexica used the sap of maguey leaves to heal

festering wounds; today's studies indicate that the same sap inhibits the growth of various bacteria associated with wounds. In another example, the Mexica used white sapote as an effective sleep aid, and modern medicine reveals that the seeds of this fruit indeed contain sedative components (de Montellano, Bernard 1990, pp. 182–185).

There was some geographic variation in the incidence of medical problems: respiratory and gastrointestinal afflictions were especially prevalent in the highlands, while parasites were particularly problematic in lowland settings. Age was also a factor: rheumatism and arthritis troubled people over the age of 30–35, young children most often suffered from diarrhea and dysentery, and some children also experienced iron-deficiency anemia (Berdan, 2014, pp. 247, 250).

Medicinal aids were often mixed into complex curative potions. Additionally, cures were at times combined with other types of remedies. One of the most popular of these adjuncts was the sweatbath, often recommended as helpful in childbirth problems, skin festering, and traumas. Practical remedies were also at times joined with divinatory and magical cures; magic and divination were used in both diagnosis and curing of certain illnesses. The Mexica believed that some illnesses could have supernatural causes; these included soul loss and the intrusion of unpleasant supernatural substances.

A preventive element is also evident in Mexica medicine. A generally adequate diet contributed to relatively low incidences of chronic diseases such as cancer and heart disease (de Montellano, Bernard, 1990, p. 121). The Mexica also put a premium on hygiene, although a good diet and/or hygiene was not always followed; malnutrition and illnesses have been detected in some skeletal and dental remains of both children and adults (Berdan, 2014, p. 250). Some specific behaviors and natural materials were earmarked for illness prevention and the maintenance of good health. For instance, one designated herb was said to aid digestion and prevent fevers, a nursing mother could prevent diarrhea in her infant by shunning avocados, hair loss could be arrested by avocado seeds, and

stammering or lisping could be avoided by weaning children at a young age. In another vein, some illnesses required adherence to strict taboos: a patient with a fever was not to eat hot tortillas or chilies, and one with a head wound was to refrain from eating fish or meat. Thus, medicine and the maintenance of health in Mexica society were complex matters, relying on a blending of scientific knowledge, behavioral conventions, and strong religious beliefs.

Applications of Mexica Science

What did the Mexica do with the vast amount of knowledge they and their forebears had acquired about the world around them? What was the purpose of the many systematic and rigorous studies they made of the heavens and the earth?

While some priests and rulers may have enjoyed the process of discovery for its own sake, it is clear that scientific knowledge among the Mexica was preeminently geared toward practical and religious applications. Long-term, rigorous observations of the heavens, and the recording of celestial movements, furnished the Mexica with temporal order. These scientific inquiries provided the basis for a sophisticated calendrical system, the ability to make appropriate seasonal preparations, and the capacity to predict and prepare for extraordinary and sometimes fearful events (such as eclipses).

The Mexica were hunter-gatherers long before they entered the Basin of Mexico and adopted a well-developed agrarian lifestyle. Bolstered by both of these traditions, the Mexica were keen observers of nature and its processes. They understood the anatomy, behavior, life cycles, and ecology of wild plants and animals. They also had a sophisticated knowledge of cultigens and drew on a long agrarian tradition of seed selection, agricultural technology, and even the ability to predict certain pertinent weather conditions from animal behavior. They applied this extensive and varied knowledge first and foremost to increase and protect their food supply.

However, natural resources also enhanced their life conditions by providing fibers, furs, and feathers for clothing and adornment; building materials for domestic and godly shelter; and precious stones and metals for ostentatious displays of social status.

Nature also provided a wealth of medicinal cures, discovered, combined, and applied successfully by specialized physicians. Administering the proper remedy to the specific ailment undoubtedly required considerable experimentation, but unfortunately the documents are silent on this process.

We therefore have quite a bit of information on the Mexica's scientific results, but little understanding of their methods. Those methods, such as rigorous naked-eye astronomy, repeated observations of earthly phenomena, and centuries-long seed selection, yielded a significant body of sophisticated scientific knowledge, applied by the Mexica to practical ends. The Mexica also consistently linked the scientific realm to the religious and utilized empirical discoveries to enhance and embellish their everyday lives on more abstract and supernatural levels.

B

Bakhshālī Manuscript

Takao Hayashi

Doshisha University, Kyoto City, Japan

The Bakhshālī Manuscript is the name given to the oldest extant manuscript in Indian mathematics. It is so called because it was discovered by a peasant in 1881 at a small village called Bakhshālī, about 80 km northeast of Peshawar (now in Pakistan). It is preserved in the Bodleian Library at Oxford University.

The extant portion of the manuscript consists of 70 fragmentary leaves of birchbark. The original size of a leaf is estimated to be about 17 cm wide and 13.5 cm high. The original order of the leaves can only be conjectured on the bases of rather unsound criteria, such as the logical sequence of contents; order of the leaves in which they reached A. F. R. Hoernle, who did the first research on the manuscript; physical appearance such as the size, shape, degree of damage, and knots; and partially preserved serial numbers of mathematical rules (9–11, 13–29, and 50–58).

The script is the earlier type of the Śāradā script, which was in use in the northwestern part of India, namely, in Kashmir and the neighboring districts, from the eighth to the twelfth centuries. G. R. Kaye, who succeeded Hoernle,

has shown that the writing of the manuscript can be classified into at least two styles, one of which covers about one-fifth of the work. There is, however, no definitive reason to think that the present manuscript consists of two different works.

The information contained in the manuscript, the title of which is not known, is a loose compilation of mathematical rules and examples collected from different works. It consists of versified rules; examples, most of which are versified; and prose commentaries on the examples. A rule is followed by an example or examples, and under each one the commentary gives a “statement,” “computation,” and a “verification” or verifications. The statement is a tabular presentation of the numerical information given in the example, and the computation works out the problem by following, and often citing, the rule step by step.

Thus, the most typical pattern of exposition in the Bakhshālī Manuscript is:

1. Rule (*sūtra*)
2. Example (*udāharaṇa*)
 - Statement (*nyāsa/sthāpanā*)
 - Computation (*karaṇa*)
 - Verification(s) (*pratyaya/pratyāyanā*)

A decimal place-value notation of numerals with zero (expressed by a dot) is employed in

the Bakhshālī Manuscript. The terms for mathematical operations are often abbreviated, especially in tabular presentations of computations. Thus we have *yu* for *yuta* (increased), *gu* for *guṇa* or *guṇita* (multiplied), *bhā* for *bhājita* (divided) or *bhāgahāra* (divisor or division), *che* for *cheda* (divisor), and *mū* for *mūla* (square root). For subtraction, the Bakhshālī Manuscript puts the symbol, + (similar to the modern symbol for addition), next (right) to the number to be affected. It was originally the initial letter of the word *ṛṇa*, meaning a debt or a negative quantity in the Kuṣāṇa or the Gupta script (employed in the second to the sixth centuries). But the initial *ṛ* of the Śāradā script has a different form. This means that that abbreviation in the Kuṣāṇa or the Gupta script became a true symbol for negative numbers in the Śāradā literature. The same symbol is also used in an old anonymous commentary on Śrīdhara's *Pāṭīgaṇita*, which is uniquely written in the later type of the Śāradā script (after the thirteenth century). Most works on mathematics, on the other hand, put a dot above a negative number.

The problems treated in the extant portion of the Bakhshālī work involve five kinds of equations, namely, (1) simple equations with one unknown (15 types of problems), (2) systems of linear equations with more than one unknown (14 types), (3) quadratic equations (two types, both of which involve an arithmetical progression), (4) indeterminate systems of linear equations (three types, including the so-called hundred fowls problem, in which somebody is to buy 100 fowls of several kinds for 100 monetary units), and (5) indeterminate equations of the second degree (two types: $\sqrt{x+a} = u$ and $\sqrt{x-b} = v$, where u and v are rational numbers, and $xy = ax + by$).

The rules of the Bakhshālī work may be classified as follows:

1. Fundamental operations, such as addition and subtraction of negative quantities; addition, multiplication, and division of fractions; reduction of measures; and a root-approximation formula:

$$\sqrt{a^2 + r} \approx a + \frac{r}{2a} - \frac{(r/2a)^2}{2(a + r/2a)}$$

2. General rules applicable to different kinds of problems: *regula falsi*, rule of inversion, rule of three, proportional distribution, and partial addition and subtraction
3. Rules for purely numerical problems: simple equations with one unknown, systems of linear equations with more than one unknown, indeterminate equations, and period of an arithmetical progression
4. Rules for problems of money: equations of properties, wages, earnings, donations, etc., consumption of income and savings, buying and selling, purchase in proportion, purchase of the same number of articles, price of a jewel, prices of living creatures, mutual exchange of commodities, installments, a sales tax paid both in cash and in kind, and a bill of exchange
5. Rules for problems of travelers: equations of journeys, meeting of two travelers, and a chariot and horses
6. Rules for problems of impurities of gold
7. Rules for geometrical problems: volume of an irregular solid and proportionate division of a triangle

All the rules of the first category, namely, the fundamental operations, occur only as quotations in the computations of examples. Many of the other rules could belong to either *miśraka-vyavahāra* (on mixture) or *śreḍhī* (on series) in a book of *pāṭī* (algorithms) such as Śrīdhara's *Pāṭīgaṇita* and *Triśatikā* (eighth century), etc., but they have not been arranged according to the ordinary categories of *vyavahāra*.

We apparently owe the present manuscript to four types of persons: the authors of the original rules and examples, the compiler, the commentator, and the scribe. Possibly, however, the commentator was the compiler himself, and "the son of Chajaka" (his name is unknown), by whom the Bakhshālī Manuscript, or at least part of it, was "written," was the commentator or one of the commentators. The colophon to the section that

deals exclusively with the *trairāśika* (rule of three) reads:

This has been written by the son of Chajaka, a brāhmaṇa and king of mathematicians, for the sake of Hasika, son of Vasiṣṭha, in order that it may be used (also) by his descendants.

Immediately before this statement occurs a fragmentary word *rtikāvati*, which is probably the same as the country of Mārtikāvata mentioned by Varāhamihira (ca. AD 550) among other localities of northwestern India such as Takṣaśilā (Taxila), Gandhāra, etc. (*Bṛhatsaṃhitā* 16.25). It may be the place where the Bakhshālī work was composed.

A style of exposition similar to that of the Bakhshālī work (“statement,” etc.) is found in Bhāskara I’s commentary (AD 629) on the second chapter called *gaṇita* (mathematics) of the *Āryabhaṭīya* (AD 499). Both Bhāskara I’s commentary and the Bakhshālī work attach much importance to the verification; it became obsolete in later times. The unusual word *yāva* (*yāvakaraṇa* in Bhāskara I’s commentary), meaning the square power, and the apparently contradictory meanings of the word *karaṇī*, the square number and the square root, occur in both works.

Bhāskara I does not use the symbol *yā* (the initial letter of *yāvattāvat* or “as much as”) for unknown numbers in algebraic equations even when it is naturally expected, while he employs the original word *yāvattāvat* itself in the sense of unknown quantities (in his commentary on *Āryabhaṭīya* 2.30). This probably implies that he did not know the symbol. The symbol is, on the other hand, utilized once in the Bakhshālī work in order to reduce the conditions given in an example to a form to which the prescribed rule is easily applicable; after the reduction, the symbol is discarded and the rule is, so to speak, applied mechanically (fol. 54^v). This restricted usage of the symbol seems to indicate that the work belongs to a period when the symbol was already invented, but not very popular yet.

There has been quite a bit of dispute over the dates of the manuscript. Hoernle assigned the work to the third or the fourth century AD, Kaye to the twelfth century, Datta to “the early

centuries of the Christian era,” and Ayyangar and Pingree to the eighth or the ninth century. The above points suggest that the Bakhshālī work (commentary) was composed not much later than Bhāskara I (the seventh century).

Balkhī School of Arab Geographers

Gerald R. Tibbetts

The Balkhī School refers to a group of four authors who recognize the fact that their geographic work is interlinked. It is also known to scholars as the Classical School of Arab Geography or the Islamatlas. Abū Zaid Aḥmad ► [ibn Sahl](#) al-Balkhī (d. 322/834), who wrote *Ṣuwar al-aqālīm*, is the earliest of them and presumably the originator. The other three authors are Abū Ishāq Ibrāhīm ibn Muḥammad al-Iṣṭakhrī (ca. AD 950) (*Al-masālik wa'l-mamālik*), Muḥammad ► [ibn Ḥawqal](#) (d. between 350/861 and 360/972) (*Ṣūrat al-arḍ*) and Abu 'Abdallāh Muḥammad ibn Aḥmad ► [al-Muqaddasī](#) (d. ca. 390/1000) (*Aḥsān al-taqāsīm*).

Their work is based on a series of maps covering the Islamic Empire together with a text which consists mainly of notes on the maps. Many copies of these works survive; the earliest surviving manuscript being a version by Ibn Ḥawqal dated AH 479/AD 1086. This is the

earliest Arabic manuscript to contain a map. Yet, copies of al-Iṣṭakhrī's book were still being produced as recently as the middle of the nineteenth century AD. There is so much material available that scholars have identified two separate editions 3ns of al- Iṣṭakhrī, three of Ibn Ḥawqal and two of al-Muqaddasī, although one of the versions of Ibn Ḥawqal does not contain maps. These different texts can be associated with similar sets of maps, and these maps can be compared and relationships established which enable us to trace the development of "Balkhī" cartography. The standard set of maps consists of a world map, two oceans (Indian and Mediterranean), four Roman provinces (i.e., areas which were originally Byzantine) and 14 Persian provinces ([Fig. 1](#)).

It is obvious that the maps are conceived as a set covering the Muslim Empire with reasonable detail, and there is no attempt to cover non-Islamic areas in the same way. It has been suggested that this policy of including only Islamic regions is deliberate. Each map is given a page or so of textual description, and each of these descriptions is planned in such a way that lists of routes, towns, mountains, rivers, etc., are given for each province. Thus they bear a certain

Balkhī School of Arab Geographers,

Fig. 1 Map of Arabia from al-Iṣṭakhrī's *Ṣuwar al-buldān*. From the Bodleian Library, Oxford. MS Ouseley 373, folio 9v (Used with permission of the library)

resemblance to the work of ► [Ibn Khurdādhbih](#), although the latter's work was not accompanied by maps nor did he limit himself only to the Dar al-Islam. There is a likelihood that the Balkhī School material and the work of Ibn Khurdādhbih are based on Persian (Sassanid) materials which survived the Islamicization of the Persian home areas.

The Balkhi maps cannot be connected together like the sectional maps of ► [al-Idrīsī](#) to form one large map of the known world. Al-Iṣṭakhrī and Ibn Ḥawqal show no interest in projection, scale, or mathematical geography and do not mention latitudes and longitudes at all. The only form of measurement given is that of days, journeys (*marḥala*). The maps are very geometrical in design. Lines are straight or arced, rivers are parallel lines, lakes often perfect circles. Towns can be circles, squares, four pointed stars or something similar. Stopping places on routes resemble small tents or caravanserais.

al-Muqaddasī's text is based on the same principles but is a considerable improvement over that of his predecessors. He also includes a section on astronomical geography and geodesy including a note on the Greek system of climates. Both ► [Ibn Ḥawqal](#) and al-Muqaddasī are more up-to-date and are more at home in Europe and North Africa, having a preference for the western part of the Empire rather than the Persian speaking areas. al-Muqaddasī's maps however have a closer affinity with those of al-Iṣṭakhrī, whereas we would expect, from the nature of his text, something much more advanced. He has however a different selection of maps, there being no world map nor one of the Caspian Sea and a completely new map of the Arabian desert.

The works of these authors were reproduced continually throughout the centuries not only in Arabic but also in Persian or Turkish translation. Other writers occasionally borrow a selection of the maps or an individual map. Some of the later versions are very corrupt and hardly recognizable. A world map derived from this school appears regularly in the works of Ibn al-Wardī and often in texts of al-Qazwīnī's cosmography showing how popular these maps were in the Muslim world.

Bamboo

David Turnbull

Architecture Faculty, Victorian Eco-Innovation Lab (VEIL), Melbourne University, Melbourne, VIC, Australia

Few other plants or materials have been so pleasing to the eye, have inspired so many artists, poets, and philosophers, or have contributed so materially to the development of civilization as have bamboos. Bamboo (*Arundinaria*) is a grass that grows with great rapidity in a wide range of climates with over 1,500 species around the world. It is both immensely strong and very light. It is easily worked with simple tools and is

strikingly beautiful both in the economy of its natural form and in its finished state. Yet not only has its key role in the development of science and technology been largely overlooked by Western historians of science, but its contemporary uses tend to be contemptuously undervalued as simple and traditional. It was dismissed as "poor man's timber."

The reality is that bamboo has been one of the prime nutrients of Asian culture and may yet turn out to have a significant role to play in civilizations around the world. The applications and powers of bamboo are almost limitless from the purely aesthetic to merely practical. The earliest boats were made of bamboo. Through inspiring poetry, metaphysics, painting, and geometry while simultaneously being the material for its production, bamboo has both created and preserved knowledge, wisdom and art. Bamboo has not only sustained life by providing housing, food, and medicine, it has been used to make a profusion of tools and domestic and industrial essentials from baskets to scaffolding, cables, and steel reinforcing, from musical instruments to windmills, bridges, and airplanes.

It was a raw material for papermaking that bamboo made its greatest contribution in the past, while also having the capacity to revolutionize paper production in the future. Bamboo is a super producer yielding two to six times more cellulose per acre than pine and can be cropped annually, but its capacity to provide paper pulp has gone largely unrecognized outside India, China, Thailand, and Brazil. Fifty percent of the world's timber is used to make paper, while in India two-thirds of the paper is made from bamboo with more than 40 factories making 600,000 tons of paper annually. If this use of bamboo were extended worldwide, the saving of old growth forest currently used in wood chip production would be greatly reduced.

In Colombia and Costa Rica, bamboo, when coated with concrete in a form of lath and plaster construction, has proved to be a cheap and effective way of building earthquake-proof housing. Similar techniques are under development in the

Philippines and Hawaii to use bamboo in cyclone-proof buildings. Bamboo has proved extremely effective in stabilizing soil and preventing erosion. As a "mop crop" it also has a great capacity to extract nitrates and phosphates from effluent. These characteristics make it an ideal plant for handling two of the world's most significant problems, soil degradation and water quality. It is the ultimate renewable resource and if it is employed in either or both these ways it can become a cheap and sustainable feed stock for making paper, houses, furniture, flooring, a profusion of decorative items as well as food and medicine.

However, it is in this transition from being virtually a free good to being a valued resource that potential problems lie. Demand is already exceeding supply in India, and while government economists in Delhi argue that bamboo can become a cash crop that will improve the lot of the poor, it is possible that the landless peasants will end up being unable to afford even poor man's timber. As Western civilization gradually overtakes the developing world, research on the more industrial uses has begun, and it is being widely used in making parquet flooring and laminated beams. It is to be hoped that, as it becomes a first world resource, it does not become just another opportunity for exploitation. If the developing economies leave the knowledge of its uses and the control of production in the hands of the local people, bamboo has the capacity to benefit all of us.

Banū Mūsā

Donald R. Hill

The Banū Mūsā were three brothers, Muḥammad, Aḥmad, and al-ḥasan, who were amongst the most important figures in the intellectual life of Baghdad in the ninth century. We do not know their dates of birth, but Muḥammad died in 873 and could hardly then have been less than 70-years old, because the youngest brother al-ḥasan was already a brilliant geometrician in the reign of ► [al-Ma'mūn](#) (813–833). Their father, Mūsā ibn Shākir, was a noted astronomer and a close companion of al-Ma'mūn when the latter was residing at Marw in Khurasan before he became caliph. When Mūsā died, al-Ma'mūn became the guardian of his sons, who were given a good education in Baghdad, becoming skilled in geometry, mechanics, music, mathematics, and astronomy.

Under the successors of al-Ma'mūn, the brothers became rich and influential. They devoted much of their wealth and energy to the quest for the works of their predecessors, especially in Greek and Syriac, and sent missions to the lands of the Byzantine Empire to seek out manuscripts and bring them to Baghdad. Muḥammad is said to have made a journey to Byzantium in person. The brothers acted as sponsors to a group of scientists and translators, to whom they paid about 500 *dinars* a month. The most outstanding of these scholars were Thābit ibn Qurra and Hunayn ibn Ishāq, who rendered numerous works, many of which would otherwise have been lost, from Greek and Syriac into Arabic. Muḥammad was on friendly terms with this group of scholars, particularly with Hunayn, who translated and composed books at the request of his patron. The brothers therefore played a leading role in the transmission of Greek works into Arabic, and in the foundation of the long and important contribution of the

Islamic world to the sciences. Some 20 works are attributed to the Banū Mūsā, of which 3 have survived. The best-known and most important of the brothers, books, which were largely the work of Aḥmad, is their *Kitāb al-ḥiyal* (Book of Ingenious Devices). The work comprises descriptions of some 100 small machines, including alternating fountains, self-filling and self-trimming lamps, and a clamshell grab. About 80 of the devices, however, are trick vessels of various kinds that exhibit an astonishing mastery of automatic controls. The inspiration for Aḥmad's work is undoubtedly to be found in the machine treatises of the Hellenistic writers, particularly the *Pneumatics* of Philo of Byzantium (mid-third century BCE) and the *Pneumatics* of Hero of Alexandria (f l. ca. AD 60). The *Kitāb al-ḥiyal*, although some of the devices in it come directly from Philo or Hero, goes well beyond its Greek predecessors, particularly in the use of small pressure variations and conical valves and other components in automatic controls. Indeed, the work of the Banū Mūsā in the variety and ingenuity of their control systems was unsurpassed until quite recent times. There may have been some didactic intention in their writing, but most of their constructions are quite trivial to our eyes. Nevertheless, many of the ideas, techniques, and components that they used were to be of considerable importance in the development of machine technology.

Barrow in China

Nanny Kim

Heidelberg University, Heidelberg, Germany

The wheelbarrow as a simple means for transporting goods has been used across much of Eurasia. The vehicle usually consists of a relatively small wheel that is mounted beneath a frame for the load. The wheel is usually placed in front or under the front part of the frame, which extends into two handles by which the barrow is

lifted up and pushed. On the basis of pictorial evidence from medieval Europe, it is assumed that the wheelbarrow was developed as a labor-saving device in which one of two men needed for carrying a carrying load was replaced by a wheel (Matties, 1991). Due to the fact that the workman had to lift part of the weight of the load, the wheelbarrow was typically restricted to short distances.

In China, the wheelbarrow is documented in pictorial sources from the first century BCE. The wheelbarrow of the Han period (206 BCE–221 CE) appears in short-distance urban transport. The vehicle has a small solid or spoked wheel that is mounted under the front third of the frame, which raises over the wheel. With the center of gravity set low, little above the wheel's axle, the tilt angle of the barrow was relatively high, reducing the weight that the barrowman had to lift while pushing. Wheelbarrows of this construction remained in use throughout the plains and lowlands of Shaanxi in the northwest across Sichuan and Hunan into Southern China (Figs. 1, 2, and 3).

From the eleventh century, a one-wheeled vehicle of a different construction appears in written and pictorial sources of Eastern China. This wheelbarrow had a large spoked wheel of

Barrow in China,

the size of a cartwheel, probably not much less than 1 m in diameter. A wooden frame was built over the top half of the wheel with platforms for the load on both sides. The outside beams of these frames extend into two handlebars for the barrowman to work the vehicle and for attaching a sling that ran over his shoulders to take the weight off his arms. The load was usually divided into two and evenly distributed on the two platforms, though bulky goods could be strapped over the top of the housing (Fig. 4).

The constructional difference from the ordinary wheelbarrow is the position of the wheel under the load. The barrowman had to balance and push the vehicle, but he no longer needed to lift part of the weight of the barrow and the load. The housed wheelbarrow constituted a gain in efficiency in carrying capacity and range. The large wheel brought reduced friction and better stability compared to the ordinary wheelbarrow, and the balanced load enabled barrowmen to work full days, making the vehicle widely employed in long-distance transport (Fig. 5).

Barrow in China,

Fig. 4 A housed wheelbarrow in a farmyard in northern Jiangxi (Drawing after Hommel (1937), plate 483)

**Barrow in China,**

Fig. 5 Wheelbarrows with small sails, no location (From Wegener, 1930, plate 15)

The technical difficulty with wheelbarrows is the wheel. In two-wheeled vehicles the wheels are subjected to torque, mainly in turns and to a lesser degree on uneven ground. In a wheelbarrow, by contrast, the wheel has to withstand considerable torque almost permanently, the impact being reduced only when the barrow runs smoothly and with good balance. The technical challenge was met by using either small and simple wheels, usually a solid disk, or alternatively by particularly strong spoked

wheels. André Wegener Sleeswyk argued that the early development of highly stable yet light spoked wheels in China, which was certainly in place by the Han period, was instrumental in the development of the housed wheelbarrow (Wegener Sleeswyk, 1982). For this reason, a transition from the ordinary to the housed wheelbarrow appears unlikely, as it would involve a gradual increase in wheel size and a shift from the front to the center of the vehicle. More probably, the housed wheelbarrow was an

Barrow in China,

Fig. 6 Recent photo of a wheelbarrow wheel, showing the segmented rim, the massive hub, and the square hole for fitting the axle

B

adaptation of the cart for crowded streets and narrow paths.

While the wheels of housed wheelbarrows are similar to those of carts in size and general appearance, their construction is simpler. Instead of turning on an axle, barrow wheels have short, fixed axles protruding from the hub. These turn in the holes of two short beams that form the basis of the frame. Wheelbarrow wheels required only a single piece of metal; they were usually fitted with an iron rim. The disadvantage of the structure was that both friction and wear in the fixed wooden axle turning in a hole were high. At the same time, the simplicity kept cost low and maintenance easy; the axle was the only piece of hardwood, and the beams to both sides of the wheel could be easily exchanged when the hole began to wear out (Fig. 6).

Through the Ming and Qing periods, the housed wheelbarrow became a widespread means of transport throughout the North China Plain and the lowlands along the middle and lower Yangzi. *Tiangong kaiwu*, a technological encyclopedia of the early seventeenth century, differentiated between a larger northern form and a smaller southern form. On the basis of this and other sources, it appears that the northern form carried some 200–250 kg and was worked by two men, for heavy loads using a donkey,

possibly even two animals. In addition, sails were mounted in windy plains for additional traction. The smaller southern form usually carried about 120 kg and was worked by a single man. In the middle and lower Yangzi region, the housed wheelbarrow became the only form of wheeled transport. In densely inhabited areas where roads served as links between waterways, the wheelbarrow was particularly well adapted, as it was suitable to narrow paths and needed no animal power that had become rare in an economic system of extremely intensive land use (Figs. 7, 8, and 9).

Housed wheelbarrows were used in goods as well as passenger transport. Passengers usually sat on the two platforms as if they were narrow benches, with a foot supported by a sling, though a riding position with the passenger sitting on top of the frame is also documented. Although rarely mentioned, it seems that housed wheelbarrows served as a common means of transport for passengers who could not afford carts, sedan chairs, or horses. It would appear that they were especially popular with women, as in Northern China foot-binding had spread almost throughout the rural population, and women consequently were poor walkers. A variant form used had a somewhat smaller wheel and a flat frame mounted on a slightly smaller wheel. The vehicle

was used in urban transport as a mobile tabletop for itinerant trade and for short-distance transport in building sites. Wheelbarrows remained in use until bicycles replaced them in the twentieth century (Kim, 2008).

Basketry in Africa

Judy Sterner

Department of Anthropology and Archaeology,
University of Calgary, Calgary, AB, Canada

The term *basketry* covers a wide range of material culture usually made out of vegetable fibers from both wild and domesticated plants. However other materials such as leather, wool, metal, and plastic may be incorporated into baskets, and baskets made of plastic-coated telephone wire are now produced in southern Africa (Cunningham & Terry, 2006; Sentence, 2001; Wendrich, 1991). Vegetable fibers are made into a great diversity of objects: baskets, bags, mats, fish traps, sieves, strainers, hats, jewelry, and more. Baskets are containers made by basketry techniques.

Basketry in Africa, Fig. 1 Mafa women making coiled baskets, Gousda, Cameroon, 2002 (Photograph: J. Sterner)

They are carried on the head or back or in the hand. They are used for storing small things and as granaries taller than a human. Mats, flat but made by basketry techniques, are used as covers for pots or baskets, to sit or sleep on, or as components of walls, roofs, and fences. Such architectural basketry also includes roof caps and related forms. All these varied objects are made by three primary techniques, coiling, plaiting, and stake and strand, all of which include variations. Definition of these techniques is based on identification of the active and passive elements that make up the basic structure of the basketry item (Wendrich, 1991, 1999). The first technique, coiling, involves a passive element such as a tubular bundle of grass that is held in place by the active element, perhaps strips of palm frond (Fig. 1). In plaiting there is no passive element but three or more active elements, often groups of grass stems (Fig. 2). The stake and strand technique combines a number of relatively rigid passive elements and more flexible active ones.

Basketry in Africa, Fig. 2 Sukur man having completed plaited basket body prepares to add frame. Note the plaited wall mat on right-hand side. Sukur, Nigeria, 1992 (Photograph: N. David)

Weaving, waling, twining, and randing are sub-categories of this technique.

Unlike inorganic materials such as rocks, metals, ceramics and mineral-rich bone and antler, organic materials used to make baskets or textiles are, unless preserved in bogs, deserts or ice, poorly represented in the archaeological record. However, Trigger (1989, p. 276) remarks that, even when basketry is found in excavations, it does not receive the same attention from archaeologists as other domains of material culture (Wendrich, 1999, p. 1). Some of the earliest dated basketry specimens (*ca.* 5900–4000 BCE) were excavated in Egypt and archaeological evidence of basketry production is sometimes found as impressions in fired clay that allow identification of manufacturing techniques (Derefaka, 1980; Mayor, 2011). In the absence of dated archaeological evidence of basketry production, Cunningham and Terry (2006, pp. 25–29) have suggested that the earliest basketry in southern Africa was made by hunter-gatherers, comprising fish traps and open-twined mats that served both as platters and as sieves to retrieve roasted seeds and larvae. Herders subsequently made mats for covering shelters, and with farmers came the proliferation of a wide variety of basketry containers and other objects. Hurcombe (2008a, 2008b) has

exploited contemporary craft production and experimental archaeological methods to study the use-wear on stone tools that may have been used for cutting plant materials for use in basket making. Museum collections, photographic archives and ethnographies are other sources of basketry documentation and history (Cunningham & Terry, 2006; Sieber, 1980; Sterner, 2012). But few published sources focus on this ancient and often archaeologically invisible craft in historic and cultural context. A notable exception is Wendrich's (1999) study of archaeological and contemporary basketry in Egypt. She documents gathering and preparation of raw materials, techniques employed, genders of producers and users, specialization and much more.

Baskets may have more than utilitarian functions. They are sometimes associated specifically with women's rites of passage. A Somali wedding basket represents the bride (McMahon, 1988; Talle, 1993); in Harar City, Ethiopia, basket-making skills and proper display of baskets were an integral part of becoming a woman (Silverman, 1999; Tarsitani, 2009). And in the Aghem-Fungom area of Cameroon, a woman's grave was marked by a basket (Geary, 1987). In the nineteenth-century southern African Zulu kingdom, waterproof baskets (in addition to calabashes) for storing and serving liquids and fiber mats for serving meat were used by commoners, whereas pottery and wooden containers were the prerogative of the royal family and associates (Leibhammer, 2005).

The study of basketry has benefited from the relatively recent development of archaeological approaches to gender, craft production, and technology. This is best exemplified in the work of Hurcombe (2007) and Miller (2007). Hurcombe examines four categories of materials: organics, stone, clay and glass, and metal. Miller identifies production technologies associated with a similar range. Both authors are concerned with gender and the apparent lack of archaeological attention to women's activities and products. Basketry and other fiber crafts are specifically referenced.

The question of the gender of basket makers and users is informed by research in the Mandara

Mountains of northern Cameroon and northeastern Nigeria, a region where women make pottery and men are engaged in iron working and other crafts. In some ethnic groups, these crafts may be dominated by endogamous (casted) specialists (Sterner, 2012; Sterner & David, 1991) (this survey is based on fieldwork by N. David and J. Sterner (1986, 1989, 1990, 1991, 1992-3, 1996, 2001, 2002, 2004, and 2008) and published and unpublished information on 25 ethnic groups in the Mandara Mountains).

Among the Mafa, the most populous ethnic group in the Cameroonian Mandara, women make coiled baskets in a wide range of sizes. They are used in the household and to carry the harvest from field to granary. Unlike pottery making, basket making is here open to all women. The plant materials are available to all. Basket making takes place in the dry season, a woman working alone at her house or with others and their children beneath a shelter. The only formal tools required are a diminutive iron sickle and an awl, often combined in a single tool made by local blacksmiths. Though some produce items for sale, baskets are primarily for the use of the maker and her family. Elsewhere in the region, young boys make coiled straw hats, and blacksmiths make tightly coiled baskets used both as caps and as cups from which to drink beer. Members of the farmer caste will not drink from the same vessel as a smith.

Among other of the culturally closely related ethnic groups in the region, including the Sukur and Kapsiki, men are the basket makers, using a continuous plaiting technique. Just as elsewhere coiled baskets can be made by any woman, here plaited basketry can be made by any man. There are societies in which both types of basket are made by women and men, respectively. In addition to plaited baskets for carrying the harvest, the wide variety of basketry includes chicken carriers, rain capes, and much architectural basketry: granary caps, roof caps, mat walling, and granaries (Fig. 3). While all men can make the large mats used as walling and roofing, a few specialize in making the baskets used for carrying the harvest. A large iron needle and a sickle or knife are the only tools needed to make such a basket and

Basketry in Africa, Fig. 3 Boy with a sample of plaited basketry from the Sukur Mini-Museum. He wears a rain cape, holding one for a baby in his left hand and a beer filter in his right. In foreground there is a rolled sleeping mat, and behind, from left to right, a basket, a food preparation mat, and a basket for carrying charcoal. Sukur, 2004 (Photograph: Judy Sterner)

related forms. However there are more materials and stages involved in basket construction (plaiting of the body, making and attaching a wicker frame, forming and covering the foot and headrest). The work takes place in the dry season often under a veranda in a courtyard, with other men socializing, making rope, and sometimes assisting. The required raw materials are available to all. The baskets and related products are largely for local consumption, with some sold at regional markets.

Large plaited mats are made here for local use and are sold widely within the region and beyond. In the colonial period, men made mats in order pay taxes and bridewealth, the practice continuing to this day as a source of cash. Unlike metal artifacts and pottery, which embody utilitarian, social, and ritual functions, basketry is largely utilitarian, though granaries are repositories of millets,

Basketry in Africa, Fig. 4 Plaited and coiled baskets outside a Hidé house, Cameroon, 1986 (Photograph: N. David)

groundnuts, and symbolic meaning (Sterner, 2012; van Beek & Avontuur, 2005). In summary, in a region where crafts are often gender specific and endogamous groups monopolize metallurgy and ceramics, both genders make baskets, though by different techniques, and the items produced serve primarily utilitarian functions (Fig. 4). Is this true elsewhere in Africa?

Associations between gender and technique are found elsewhere in Africa, as is revealed in a survey of ethnographies and other sources on 23 societies/ethnic groups containing information on basketry techniques, uses and the gender of producers (Sterner, 2012). Cunningham and Terry's (2006) extensive study of southern Africa covers plant materials, the techniques employed and the uses and changes in basketry use from 1850 to present. There are descriptions of

Basketry in Africa, Fig. 5 Mafa coiled baskets with harvested sorghum ready for transport, Gousda, Cameroon, 2002 (Photograph: J. Sterner)

basketry techniques used by many ethnic groups and excellent photographs (some from archival sources) of men and women engaged in basket making and use. Unfortunately there is little specific reference to gender. Perhaps this was a wise choice as there is some controversy in the literature on Zulu basketry as to whether in the past men or women were the primary basket makers, or whether such rigid gender categories existed among early Zulu basket makers (Krige, 1950; Leibhammer, 2005). A wide range of basketry objects are made, using the three primary techniques of coiling, plaiting and stake and strand. Sometimes it is men who use the coiling technique, at other times women. It is not unusual to find that in a single society both men and women are basket makers, with each using a different technique. For example in Kenya, Kikuyu women make plaited and men coiled baskets (Ocholla-Ayayo, 1980). Conversely among the Goula of Chad, men practice plaiting and stake

Basketry in Africa, Fig. 6 Sukur houses with plaited roof and granary caps, some recently renewed, over thatching, 1991 (Photograph: N. David)

and strand, while women coil (Pairault, 1966). Here basketry is used for transporting items, storage, fishing, architecture, as mats and covers, hats, and more (Fig. 5).

There is great potential to develop new methods that do not rely on organic remains to determine the presence of basketry in archaeological sites. This is important since basketry production systems and the nature of their products do not duplicate variation in other domains of material culture but provide new and different perspectives and insights into society, culture, and the ideational world. In addition, basket makers in Africa and elsewhere make use of a huge range of plant species and have been described as caretakers of biodiversity (Novellino & Füsün Ertug, 2006). It is not surprising that in 2005 the IVth International Conference on Ethnobotany hosted a symposium on basketry. The study of basketry opens windows into both nature and culture (Fig. 6). There is indeed a “world according to basketry” (Wendrich, 1999).

Basketry in Ancient Egypt

Willeke Wendrich

The oldest basketry found in Egypt dates to the Neolithic period (ca. 5900–4000 BCE). In the Fayum Oasis, about 100 km (60 miles) southwest of Cairo, grain storage pits were excavated in the desert floor, lined with coarse straw basketry (Fig. 1).

First discovered in 1926 (Caton-Thompson & Gardner, 1934) and examined in detail for the first time in 2005 after recent excavations (Wendrich & Cappers, 2005), these baskets represent a coiling technique. This entails a bundle of straw fastened into a coil with a number of stems pulled out of the straw bundle at regular intervals. This particular type of coiling went out of use and was replaced by a variation of the

coiling technique, which existed simultaneously. This type of coiling makes use of different materials for the bundle and the winders (Fig. 2).

Near the Neolithic grain storage pits part of an extremely finely coiled basket was found, dated to about 4200 BCE, made of separate bundle and winder materials and decorated with darker winders along the rim (Fig. 3).

These two examples from the Egyptian Neolithic demonstrate that basketry technology was well advanced by that time and must have known a long period of development for which we have no other evidence.

Basketry in Ancient Egypt, Fig. 2 Coiling with separate bundle and winder materials. A bundle of grass is held into place by palm leaf winders

Basketry in Ancient Egypt, Fig. 1 Neolithic grain storage pit lined with coarse coiled straw basketry, excavated in 2005 (Photograph UCLA/RUG Fayum Project)

Basketry in Ancient Egypt, Fig. 3 The Fayum Neolithic produced very fine decorated coiled basketry. This 6,000 year old fragment was found only a few centimeters under the surface (Photograph UCLA/RUG Fayum Project)

Basketry in Ancient Egypt, Fig. 4 Three examples of the many variations used to produce twined basketry: **a** a mat made of bundles of grass, fastened into a fabric with

widely spaced rows of twining; **b** a sturdy mat made of narrowly spaced twined string, and **c** a sieve grid made of open twined strips of palm leaf

The oldest and most frequently used techniques in ancient Egypt were coiling, twining and mat weaving. Coiling was used to produce sturdy baskets, varying in size from 3 to 60 cm in diameter. In Ancient Egypt wood was scarce. Basketry, therefore, had an important function, replacing cupboards as containers for clothing, food, and many other items. The tomb of Tutankhamun contained over 120 baskets (Reeves, 1990, p. 204; Malek). Even coffins and sandals were made in the coiled technique.

Twining has been attested from the Predynastic period onward. The twining technique consisted of a (passive) warp and a weft of two active strands. These were twisted around the passive warp elements, and each other, in either S or Z orientation. The twining technique was extremely versatile, depending on the materials used and the distance between the weft and warp elements. Figure 4 shows some of the variety.

Matting was used widely as awnings, wind-breaks and doors, but also as mattresses for sleeping and covers to wrap the dead. Egyptian architecture was characterized by many references to the use of mats in the original shrines and temples. The “drum” that was part of the so-called false door represented a rolled up mat, and decorative motifs on tomb and temple walls, such as pillars carved to resemble tied reed bundles, a stylized motif representing the tied off bundles of grass matting (the *kheker* motive) and

other decorative patterns, also referred to mats. The Djoser complex in Sakkara, for instance, displayed many references to the perishable predecessors of its stone architecture (Lehner, 1997, pp. 84–93; Verner, 2002, pp. 108–140).

For mat weaving a simple horizontal ground loom was used, consisting of four wooden pegs in the ground, to which two crossbeams were tied. The warp was kept taut by tightening the strings tying the two beams to the ground pegs. A third beam, with evenly spaced holes, guaranteed the regular spacing of the warp string (in more delicate loom types this part would be called the *reed*). It had a double function, because by slamming the beam into the woven part of the mat, it also served as a beater, creating a tight weave. The mats were mostly made with a warp of grass string, spaced 3–4 cm apart, and a weft of single grass stems, or small bundles of grass. For sleeping mats the grass was laid in with the thicker base side of the stem, while the tip was left to stick out from the warp, forming a more comfortable thick fibrous pad underneath the mat. An early depiction of a mat weaver is found in the tomb of Khety in Beni Hassan and dates to the early Middle Kingdom (ca. 1900 BCE, see Fig. 5).

From approximately the fourth century BCE onward the plaiting technique became increasingly popular in Egypt. Sandals were no longer made of many parallel rows of coiling, but rather plaited with palm leaf. The equivalent of

Basketry in Ancient Egypt, Fig. 5 Tomb painting of a mat weaver (detail), dating to the Middle Kingdom (approximately 1600 BCE). From the tomb of Khety in Beni Hassan, Middle Egypt

our flip-flop was plaited with eight strips of doam palm leaf, each approximately 4 cm wide. More elaborate sandals had several padded layers, of fine and coarse plaiting with different materials: coarse plaits from palm fiber for the outer sole, fine plaited palm leaf fabric for the inner sole. Fans were made of extremely fine plaited matting, using strands of palm leaf of only 2 mm wide. For both mats and baskets a completely new technique was introduced into Egypt, consisting of plaited strips sewn together to form a seemingly ongoing plaited fabric. Depending on the pattern, only twill strips plaited with a particular number of strands (9, 13, 17, 21, etc.) could be used, which created broad edges, with a particular orientation. The edges were pulled inside each other, thus completely hiding the sewing strand. The most commonly used materials for basketry changed slightly over time. In the prehistoric and Predynastic periods the materials attested are papyrus (*Cyperus papyrus*), the stems of the composite *Ceruana pratensis* and wheat or barley straw. In the Pharaonic period tall tough grasses (*Desmostachya bipinnata* and *Imperata cylindrica*) were used for twined and woven matting, as well as for the bundles of coiled basketry. The coils were fastened with winders of papyrus rind or doam palm leaf (*Hyphaene thebaica*). Date palm leaf (*Phoenix dactylifera*) occurred

rarely in the Pharaonic period, but became widely used toward the Late Period and the Greco-Roman period, taking over the significance of both papyrus and doam palm leaf. This probably had an environmental reason; a slight climatic change caused the doam palm to retreat south and at present this species occurs only sparsely south of Luxor and is common only in Sudan. The date palm, on the other hand, was cultivated increasingly in all of Egypt. Similarly, papyrus plants, cultivated for writing material and basketry, withdrew to the south and at present do not occur in a natural habitat in Egypt.

The variety of ancient Egyptian basketry techniques, shapes, and materials reflect the widespread use and functionality of these objects. The tomb paintings and reliefs from all periods of Egyptian history corroborate the information from the archaeological material. Bearers of offerings were shown carrying baskets full of produce and goods, farmers were depicted sowing from twined baskets, loading the harvest in enormous carrying nets and carrying the threshed grain in baskets to the granaries. Perhaps the most telling was the fact that in many of the ostraka (pot sherds and lime stone chips used as scrap paper) from the village of Deir el Medina baskets (of grain) were listed as the standard size for paying wages.

Basketry in Japan

Mary Butcher

Honorary Research Associate, Anthropology,
University of Kent at Canterbury, Kent, UK

Basketmaking in Japan has a long vernacular tradition, using the abundant bamboo for much of the work, this being replaced by creepers, willow, and other materials in the north where forests are coniferous and by palm and other tropical and subtropical materials on the southern islands of Okinawa. There were strong local traditions making functional baskets for the local village and surrounding areas, each being tailored for its use. There was a large range of domestic ware, for steaming, drying, storage of food, and clothing, for cradles, and many other purposes. Animal husbandry also demanded a great many baskets for gathering and carrying foodstuffs, for transport to markets, and for caging. Fishing had a wide and fascinating variety of traps, differently shaped for different species. Fish carriers often put them into water to keep the fish fresh and used scoops for transfer to the cooking pot. Gathering human food also required a wide range of special basket forms. Hip baskets were used for mushroom gathering in the bamboo forests. Back baskets were used in great variety for carrying wood, food, and animal feed when climbing up and down forest hills, leaving hands free for picking and safety. String bags, the equivalent of our plastic ones but very beautiful and well made of local fibrous plants, would also have been used all over the country for many purposes. These stems and roots, which were prepared in a number of ways, were made into cordage then woven in a vast number of different patterns.

In 2005, on a basket research trip to Japan in preparation for the co-curation of a touring exhibition “East Weaves West: Basketmaking from Japan and Britain” 2007, I was lucky to meet one of the best known vernacular basketmakers, Kazuo Hiroshima, in Hinokage, his home village on Kyushu. His work had become well known through the collection formed by the local grocer, Kenji Nakamura, with whom we stayed (Fig. 1). Kazuo Hiroshima had been apprenticed in his teens, making baskets and traveling with his teacher, weaving whatever it was that local farmers needed. He continued this itinerant life, only settling in one place during the Second World War, when he was drafted into a town to make essential containers. He was able to make many designs and became convinced that he should make these to the very best level of his skill, with attention to detail, very fine strips, and good proportions. His examples in the Nakamura Collection show this precision and artistry on these very practical baskets, and they have been exhibited in the USA and the UK as supreme examples of their kind. I was able to talk to him about his material, the bamboo from the local hillside, and hear his passion for it, the qualities of different parts of the pole, where the best gathering was done.

Such trained basketmakers would have been a common sight in rural Japan, providing the populace with the variety of carriers they needed, coming regularly to replace worn items, and able to redesign structures for new uses as country and urban life changed. The basketmaker must be a versatile craftsman, working to customer demand, in order to make a living. In addition many rural residents would have been able to make forms of containers for themselves as they needed them, a range of essential ephemeral containers. The basket was ubiquitous and vital for daily life.

On my trip I also, by pure chance, met an urban basketmaker working not far from Shinjuku Tower, in downtown Tokyo, a very unexpected sight. Shouten Yoshida is an artisan basketmaker working in a small glass lean-to next to his house and selling from a small wooden

Basketry in Japan,
Fig. 1 Kazue Hiroshima
 large backpack

B

Basketry in Japan, Fig. 2 Shouten Yoshida in his workshop

shed on the pavement (Fig. 2). He also makes a wide range of carrying baskets, for animal feed, food, and domestic ware, and a range of bamboo scoops for rice, mushroom sieves, and ladles, but

these are more rapidly made than those of Kazue Hiroshima, with coarse splits of bamboo. We watched him preparing these, first splitting the pole with a 12-bladed tool which is hammered down the pole. The resulting strips are then scraped on the inside to remove the softer central parts and the nodes, making them thin enough to weave, and then they are taken between two precise vertical blades to make the strips a uniform width along their length. His dust scoops, backpacks, and hip baskets were functional and immensely strong. Such urban basketmakers would have been a common sight in all towns, again using whatever material was available locally.

Further north, in Yokote, near Akita, where there is no bamboo, I met an urban basketmaker, Shin-ichi Nakagawara, making only two designs for the local market and with a 5-year waiting list because of their strength and long-lasting qualities (Fig. 3). He learned from his father and is proud to continue the tradition, using vines he gathers in winter from the local mountains, which is hard work for a precious material. It is carefully stored and soaked before use. He works in a corner of the main room in his house; his elderly mother cuts the material to length as she had done for her husband. His wife is also fully involved, completing the baskets with a thick, strong, beautiful rounded border. He makes several sizes of shopping baskets to the same basic

Basketry in Japan, Fig. 3 Baskets by Shin-ichi Nakagawara

plan and small baskets for sweets and fruits. He is proud, with reason, of their quality, each being woven immaculately. I was impressed by the use of every scrap of material, short trimmed ends being packed in to thicken the border; nothing whatever was wasted.

A more formalized way of learning the range of traditional techniques is taught at the Beppu, Kyushu, school for basketry, which has been running in various transformations since 1902 as a technical training support center for artisans. In the 1950s cheap plastic containers replaced many of the simple bamboo wares, so more effort was put into making high-end beautiful things showing the highest levels of craftsmanship. Since 1979 the school has been supported by the government to protect Japanese traditional bamboo arts and crafts and offers a rigorous 3-year training (Fig. 4). The system demands absolute discipline, with a defined program of work, from the

Basketry in Japan, Fig. 4 First-year students at the Beppu bamboo school 2005

simplest open hexagonal plaited dish to individually designed high art baskets by the end of the course. There is a sample room of individually designed furniture and domestic accessories, decorative items, baskets for the tea ceremony, and a multitude of less traditional uses for bamboo. Shono Shounsai, from Beppu, became the first bamboo artist to be made a Living National Treasure, the highest honor for a Japanese craftsman.

Much high art basketry, highly individual and with a specialist clientele from the Imperial Palace and its connections, is made in workshops led by a famous master. This demands a 10-year training with initial emphasis on splitting the bamboo to perfection before using it for personal, often complex designs. Works are destined for

B

traditional activities, flower arranging, and tea ceremonies and as art pieces for exhibition both in Japan and abroad. In the USA, galleries such as the Tai Gallery in Santa Fe specialize in exhibiting the work of particular bamboo artists, work that is highly prized and actively collected. Much of this work is highly sculptural, three-dimensional drawing, with the finest possible skill and exquisite detail. Ties, knots, bindings, and alignment of the node points are all considered, as is the balance and spatial nature of each piece. Leonard Cotsen has a fine extensive collection of this work which is exhibited regularly and catalogued with detailed information, a valuable reference. In 2007 a British Museum exhibition “Crafting Beauty in Modern Japan,” to recognize 50 years of the Japan Arts and Crafts Society exhibitions, brought examples to London to supplement examples already seen in the Victoria and Albert Museum (V&A) and the British Museum’s permanent collections. The exhibitors, many being holders of “intangible cultural properties,” have dedicated their lives to their work, many learning from generations of family or in the master-led workshops which is still largely a male preserve (Fig. 5).

High art basketmakers outside the Japan Arts and Crafts Society cannot become Living National Treasures but make work of the same

caliber and beauty with their own system of awards. Apprenticeship is often family based, passing on skills developed by several generations. I was fortunate to meet Tanabe Chikuunsai III, a third-generation fine art basketmaker and trainer of apprentices, and his wife who is also involved in the running of the workshop. Each day is a disciplined one with an early start in the workshop and formality and quiet for complete concentration on the basketmaking. Their son, Tanabe Shouchiku, trained in part outside the family and also went to art school to gain a degree in sculpture. Bamboo is his passion but his work has two strands, all using his high levels of skill but with different scales and outcomes to the work. During the day he works in the family workshop and makes baskets of his own design but based on the family tradition, using family techniques developed over the generations. Many of these are appreciated and bought directly by collectors or else they go to the US for exhibition. During the evenings he creates his own more personalized, self-expressive weavings, this work going to permanent collections in museums across the world. He is already very well known with his work much sought after (Fig. 6).

Tanabe Shouchiku is one part of the “New Bamboo” contemporary work, based on traditional skills but with a new outlook and free

personal expression. He is also one of a wave of bamboo artists making large-scale installation work of a sculptural nature and often site specific. For “East Weaves West” he brought, ready prepared, strips of bamboo to weave a flower shape with a central vertical section holding the flower form off the ground (Fig. 7). It was a delightful coincidence that Lee Dalby, the UK maker commissioned to make a gallery installation alongside, came up with a closely related

shape, without any prior consultation (Fig. 8). The two works, from east and west, looked very harmonious together.

Ueno Masao has long been well known in this sculptural, installation field with trips abroad to make his sometimes huge, always striking, pieces. He trained as an architect, also learning wood skills and traditional basketmaking. His work involves the manipulation of bamboo to create form and space in a wonderful way and he often describes them in mathematical terms. His installation for the Sainsbury Centre for the Visual Arts, University of East Anglia, UK, for the exhibition “Basketry Making Human Nature” 2011, arrived packed in one moderately sized suitcase, all preplanned and prepared to be assembled on site into the tangents of a huge circle. The effect was magical as the light changed through the very large window where it hung, as appealing from inside as out (Fig. 9). He has worked in a number of European Sculpture Parks and enjoys being alongside others working in a similar way, all highly focused.

In Japan, as in Europe, contemporary basketry has emerged and is thriving. Both stem in part from the work of Ed Rossbach in California, teaching fiber arts to university students in California and having a widening influence across the basketry and textile worlds. A strong fiber arts

movement with textiles and baskets, made with a rich selection of threads and wires, barks, and tapes, with techniques from round the world, grew steadily from the 1950s onward and

Basketry in Japan, Fig. 10 Hisako Sekijima basket 1990s

changed our perceptions of what these articles could be. Hisako Sekijima spent some time in the USA and became involved with this movement, meeting the makers, working with John McQueen, and developing her own strong practice of contemporary works for exhibition (Fig. 10). On her return to Japan, she started teaching and gathered an enthusiastic, talented group of young makers who were using her ways of thinking and a wide range of techniques and materials and who explored their own pathways. This group has slowly expanded and has exhibited regularly in Tokyo, Kyoto, and

Basketry in Japan,

Fig. 11 Work by Ueno Masao, window at the Sainsbury Centre, University of East Anglia, 2011 Photo Andy Crouch

elsewhere, and they are an influence on more recent work across Europe and the USA. Hisako, calling herself a “basket thinker,” has a shrewd perception of both structural analysis and her natural materials, many of which she grows in her own garden or gathers locally. It is a stimulating scene. In the UK we have been influenced by her ideas as a result of a master class I was asked to organize for her at the V&A, her teaching at Manchester Metropolitan University, and by further visits with “East Weaves West.”

Two members of this contemporary weaving group have recently been involved in the reproduction of archaeological basket remains, analyzing their structures, materials, and final forms. This is painstaking work, with a need of skilled observation and interpretation, only possible with wide existing knowledge. Kazue Honma and Noriko Takamiya worked on the remains of 7,500–8,000-year-old baskets from the late phase of the initial Jomon period. Although squashed, the baskets were in good condition, made of split wood, and had probably been used for acorn storage (Fig. 11). The materials were identified as unlike those used anywhere in Japan more recently. This evidence of the ancient nature and high skill levels of basketmaking in Japan completes the picture of a country weaving diverse containers of many materials and with a wide range of techniques over centuries. Those

makers still keeping these skills alive in variety will provide valuable possibilities for adaptation and development for future changing needs and circumstances.

The meaning of the word *basketry* includes the skill of making baskets, the making techniques, and the group of finished objects. These objects were made from raw vegetable materials, sometimes without previous preparation process. Baskets are often made with the hands. Basketry fulfilled several needs, including plateaus, spheres, and roofs. However, there are only a few remains of these because they were made from perishable materials.

Techniques

The basket-making techniques can be classified according to the materials used.

Basketry can be classified into three types of techniques: *twining*, *coiling*, and *plaiting*.

In twining, the warp is usually in a vertical position and is a passive element. The weft consists of two or more flexible weaving elements and the folded weft passes in front of and behind the warps acting as an active element. The loom lies horizontally.

In coiling, the active element or stitch is vertical and the passive element or stitch is vertical

and the passive or foundation is passive and horizontal. The stitch is always only one element. It can be defined as the sewing of a horizontal static element called the foundation, moving vertically an element called stitch.

In plaiting, both elements – warp and weft – are active elements and they are usually made from the same material and are both of the same shape.

Antiquity and Permanence of Basketry in South America

Basketry is a very ancient process and it is one of the widest spread crafts in the world as it is in South America. Archaeological research in Patagonia, Argentina, documents the presence of baskets in hunter-gatherer campsites as early as 3,000 years ago (soil layer 3, Campo Moncada 2 site, Chubut, Argentina), and there were also some other baskets dated to 500 years ago (soil layer 3, Piedra Parada 1 site, Chubut). Additionally, there were archaeological remains in sites of the region that demonstrate the existence of raw material suitable for this activity during the entire existence of life on earth. For instance, in Campo Nassif 1 (Onetto, 1986–1987), rock art dated 480 years A.P. $\pm$ 75 (INGEIS665), there was vegetable evidence of camp fires, rough grass beds, sediments from holes, and crafts (little swaps with paint residues, knitting needle of the *Schinus molle* thorn, grass balls, and pieces of brushes). However, now basketry crafts (all the artistic expressions) have disappeared (baskets, plateaus, threads), and there is no record of them in any of the ethnographic researches made in Patagonia during the last century.

This situation is different in the north of Argentina and in the Andina region. In those areas, villages and indigenous cemeteries have been subjects of archaeological research since the end of the nineteenth century. The dry environment of the region and the conditions of the crafts (stone constructions with roofs and doors made of teasel, where they were buried with their grave goods) preserved the crafts that had been

made of perishable materials such as textiles (tissues of animal fiber or basketry and ropes of plant materials).

In the days when European empires conquered America, the weaving industry was the most important local good for export. Basketry and cordage were essential for the delivery service of other goods between both continents. They were parts of the maritime environment of those first years of trade, and they arrived in America at the request of the newcomers or for business needs such as the need for lightweight and unbreakable containers for storing and transport.

That is the reason that we can find handmade products in every part of America (basketry, woven, or ceramics). Research confirms the presence and use of techniques that were mixed with other techniques provided by Europeans during the days of the colonials. This first contribution was made from the Iberian Peninsula and some centuries later some techniques were brought by immigrant communities in different parts of Europe and Asia, although to a lesser extent.

American traditional craft in general and especially in Argentina is the result of the interlinking of techniques, raw materials, and styles that formed a new reality.

Inca Cueva (Inca Cave): First Basketry Vestiges in the North of Argentina

In 1973 Aguerre, Fernandez Distel, and Aschero published their research about the information obtained during the finding and excavation of Inca Cueva site, cave 7, located in Quebrada de Inca in Tucuman province (Fig. 1). It was interesting because of the special location and the size and structure of the soil. There was a deep bore hole 2.30 m high by 3.20 m long and 3 m deep; over 3,860 m were above sea level in a heavily skewed rocky slope of Quebrada de Inca Nueva. In this Quebrada they found evidence of hunter-gatherer early settlements (Inca Cave 1 and Inca Cave 4, for instance) (Boman, 1908; Cigliano, 1965; Fernández, 1968–1971). Recovered

Basketry of South America, Fig. 1 Inca Cueva site (Jujuy)

Basketry of South America, Fig. 2 Front and back side of a plateau basket (a) of Inca Cueva 7 (Jujuy)

remains in IC C7 were settled between quartzitic stones encased in a tightly stuffed straw of 60 cm thickness called soil layer 2. One thing that caught the attention of archaeologists was the variety and quality of the crafts. These findings were not usually observed in other archaeological sites: lytic stone, textiles and basketry, leathers, wooden, stone, and bone devices, pumpkins, and ornaments. All remains were in an excellent state of conservation and many of them were decorated.

These are the remains made with vegetables as raw materials:

Plateau Basket (a). The plateau has a diameter between 74 and 78 mm, slightly concave of 22 m high and 6 m deep. The manufacturing techniques consist of a closed spiral made in a simple stitch without interlocking warps, with a cleft in its foundation. In the last two coils because the stitches are worn out, we can see the foundation and it is a bunch of grass with an “S” shape. There were two spirals per cm, stitches are 3 mm wide, there is no space between them, and there are four stitches per cm, with a “Z” shape that implies that the craft tends to be on the right. It has a standard foundation and it has no edge. It might have been painted or dotted with some product. It has adherent material on its front side (Fig. 2).

Plateau Basket (b). The plateau has a diameter between 77 and 73.5 mm, slightly concave at 9 mm high. The manufacturing techniques are the same as in the before mentioned plateau basket. Three coils per cm can be counted. The simple stitch has a “Z” shape, which means that the craft tends to be on the right as in the previous craft. Stitches are between 2 and 3 mm wide with three stitches / cm. The poor condition of the craft means we have to do more research. Both the foundation and the edge are absent (Fig. 3).

Bunch of Tied Grass. Its size is a square of 45 by 23 mm. The diameter of the bunch varies between 8 and 9 mm. It is strongly tied in the center with a string 2 mm wide above which a cord of 2 mm was placed. It was very well preserved (Fig. 4).

Bunch of Fastened Grass. Its size is 210 mm per 39/19 mm with a depth of 17 mm. It is composed of a whole gramineous plant (it keeps its root, the base of the bush, and the shaft of the leaves), folded on itself in one crease. It is all wrapped up with a juncaceous leaf that surrounds the bunch (Fig. 5).

Bunch of Feathers and Hair. It is 160 mm long, 19 mm high, and 10 mm deep. It is composed of three feathers tied with a strap by the base of the rachis. A hair fleece of a reddish

Basketry of South America, Fig. 3 Front and back side of a plateau basket (b) of Inca Cueva 7 (Jujuy)

Basketry of South America, Fig. 4 Bunch of tied grass of Inca Cueva 7 (Jujuy)

brown camelid is resting on the shaft of the feathers tied up with one juncaceous leaf that surrounds the whole bunch several times (Fig. 6).

Woody Stem Wrapped Up with Flat Basketry. It is 150 mm long and 10/11 mm in diameter. The stem has both sides carved: a blunt one and sharpened one; it is completely surrounded by various parallel rachises, making the warps. They are joined between themselves by a weave composed of two cords that always go over three warps and under, alternatively, four or five warps shaping a spiral. The thread of the weave has an S shape. The first part is a whole lap with simple twined technique. In the second one both elements become one element for the rest of the work of flat technique. The last part is made by

turning several laps over the warps and shaping the weave around itself (Fig. 7).

This combination allowed the authors (Aguerre, Aschero, & Fernández Distel, 1973, p. 229) to date it to the second millennium BC and to connect it with archaeological sites in Argentina and Chile, belonging to the Late Preceramic Period with a high specialization, and to link it to the introduction of cultigens in the Andean foothills and the West Coast Area.

The researches carried out in the Quebrada de Inca Cueva continued until 1979 with the excavation of Inca Cueva 4. The majority of fragments of animal fibers cords and leather cords (120 specimens) and, to a lesser extent, basket fragments (12 made with the twined technique and one with the plaited technique) could be found (Fig. 8). In this site there were no found fragments using the spiral or coiled technique.

Layer 2 of IC c4 had four radiocarbon measurements; the result of the oldest one was 10.620 ± 140 A.P. (LP-137) and the result of the newest was 9.230 ± 70 A.P. (CSIC-498). Meanwhile, IC c7 had two measurements: layer 3b was 4.080 ± 80 A.P. (T-1773) and layer 2: 4.030 ± 80 A.P. (Beta 64938) (García, 1997).

The evidence of these two basketry groups of the Quebrada de Inca Cueva is essential for the study of these techniques during the Argentinean

Basketry of South America, Fig. 5 Bunch of fastened grass of Inca Cueva 7 (Jujuy)

Basketry of South America, Fig. 6 Bunch of feathers and hair of Inca Cueva 7 (Jujuy)

and American prehistory. According to the last one dated, these groups and Daisy Cave basketry in California (USA) belong to the same period of time. These are the oldest crafts founded in these continents, and they belong to one of the first periods of land occupations, during the Paleo-Indian period.

Types of Existing Traditional Basketry

In Belen village (province of Catamarca, Argentina), there is a kind of traditional basketry with symbols (*Pennisetum* sp.). They are similar to the ones found in the north of the province, in los Valles Calchaquies. Economic needs and ship bonds favored the communication and the learning of these manufacturing techniques and the use of natural resources (Figs. 9 and 10).

Different types of vessels (bread basket, baskets, dipper with cover, dresser-basket or wardrobe, trivets, etc.) were made mixing two techniques: plaited or plaiting basketry and twined or twining basketry.

Craftsmen collect the symbol, which grows on the margins of rivers in open lands. That means that the cost of raw materials will depend on the effort and time needed to acquire them and that will depend on the transportation cost. Many of these goods will be held in the fairs that are organized throughout the year across all regions.

In these fairs the visitor can observe the complete manufacturing process and ask craftsmen for some shape, size, and function variants (Fig. 11).

Tracking the “Invisible” Traces of Basketry Production in Argentina, South America

The survival of materials through time is a fundamental condition for archaeological research. Because of its organic nature, basketry requires the combination of certain environmental conditions for proper preservation. Ambient temperature and humidity are key factors. That is the reason that in extremely warm and humid contexts, for instance, this kind of evidence hardly survives. However, in some cases it is possible to gain knowledge of ancient basketry practices from the recovery of the so-called indirect evidence of this material.

We refer to those situations when the basketry, or just a part of it, has been preserved under special conditions in the form of impressions (or negative imprints) on the surfaces of more long-lasting materials, such as pottery, consolidated sediments, and heat-altered clay or mud (Fig. 12).

These impressions constitute the indirect conservation of basketry structures and may respond to either deliberate actions (related to techniques visual representational and/or productive) or as a result of accidental causes. Records of this kind of findings can be found in western Argentina, in the area known as “The Lowlands” (Chaco-Santiago plains, north of Cordoba, and Misiones, Corrientes, and Entre Ríos provinces), where several archaeological cases have been mentioned (Calo, 2008; Fabra & Laguens, 1999; Gardner, 1919; López Campeny, 2010, 2011; Serrano, 1945; Tarragó & Renard, 2001) (Fig. 13).

Basketry of South America, Fig. 7 Woody stem wrapped up with flat basketry

Basketry of South America, Fig. 8 (a, b) Pieces of the twining basketry of Inca Cueva 4 (Jujuy)

Negatives and Positives: Potential and Constraints of Impression Analysis

Thus, as impressions are negatives of the original structure of the basket, the first step in any analysis should be the production of a cast or “positive” from the negative mold on the pottery. Regarding this methodology, a number of products have been tried (gypsum, clay, epoxy resins, silicone, and dental alginate), all of them having advantages and constraints (for a synthesis, see López Campeny, 2011). Furthermore, strict work protocols were elaborated to recover as much information as possible from the impressions while preserving the archaeological materials and avoiding contaminating the remains with

the substance used for the casts (Minar et al., 1999; Rieth, 2004) (Fig. 14).

The second step involves the systematic analysis of the morphological and dimensional attributes in the impressions’ casts. This study gives rise to some interpretative aspects, among which the following are worth mentioning.

Firstly, it is possible to identify the structure impressed on the cast. The structural organization of a piece results from the use of one or more techniques, that is, the set of proceedings used to manipulate the elements. Consequently, it is strongly related to the production process. Hence, recognizing the structure allows us to infer the techniques and instruments used for the manufacture. Conversely, certain properties

Basketry of South America, Fig. 9 Dresser-baskets in plaiting technique and the diagram of a plaiting structure

Basketry of South America, Fig. 10 Foundation of a basket in twining basketry and the diagram of a twining structure

and attributes of the structures (flexibility, resistance, spacing, and thickness) suggest functions associated with basketry (containers, nets, and clothing). In the case of pottery items modeled on complete baskets, it is also possible to reconstruct the containers' form and estimate their size.

Additionally, the overall state of the basket or fragment (damage, missing elements, and wear and tear) may indicate restoration or reuse of pieces which had been previously discarded or recycled from their original function to be later used in the pottery production process (Fig. 15).

The information derived from the fibers, though limited, may indicate its animal or vegetal nature; occasionally, the use of leaves or wood elements can also be distinguished (Fig. 16). An integrated analysis of archaeological evidence, document sources (both historical and ethnographic), and resources available in the area defines a preliminary database of possible raw materials to derive working hypotheses.

Concerning visual perception, patterns defined by color cannot be derived from the impressions. Neither the reverse nor a section view or the borders and finishing are accessible,

Basketry of South America, Fig. 16 Cast in which the use of woody elements and flexible fibers is observed

except in some exceptional cases. Nevertheless, designs or stylistic patterns may be identified when they respond to different structural effects, such as the use of several raw materials and certain techniques like patterned spacing, divergent stitching, and textural variations (Fig. 17).

Furthermore, the integrated analysis of technological-structural attributes could be used to characterize certain basketry traditions or “production styles,” materialized in learnt manual actions passed down through generations.

Finally, some features of the impressions provide information about certain aspects of basketry (as well as pottery) production. For instance, we can make estimates regarding the production scale (household, specialized craft)

or the preference for specific structures to manufacture certain pieces, reflecting a systematized or standardized production.

From Long Lasting to Perishable: Results of a Study Case

From the actual analysis of basketry impressions preserved on the surface of archaeological pottery, it is possible to figure out aspects related to the practices of the communities who lived during pre-Hispanic times in what is today the Argentinean Western Lowlands (López Campeny, 2011).

First, we identified several basketry structures, performed by the manipulation of vegetal resources with different properties – rigid to semirigid (rods) and flexible (fibers) elements – in areas with limited direct archaeological evidence. Twining structures were dominant, presented in many subtypes such as simple, diagonal or twill, and wrapped twining (Adovasio, 1977; Pérez de Micou, 2005), with different spacing between elements and both twist directions (right and left) (Fig. 18).

The identification of wrapped twining in the materials from Santiago del Estero indicates a connection with other archaeological assemblages, defining a wide dispersion area for this structure (Jujuy, Tucumán, Catamarca, Córdoba and La Rioja provinces) (Figs. 19 and 20).

Basketry of South America, Fig. 17 Divergent stitching and patterned spacing that make zigzag designs or diagonal lines

Basketry of South America, Fig. 18 Examples of some structural types and varieties identified in the sample

This technique would have been used to manufacture some peculiar artifacts; the so-called tipa baskets, which are still crafted in the central-western region of the country, are quite

similar to the archaeological specimens found (Fig. 21).
Based on the record of shared technological practices and traditions, we may think these

Basketry of South America, Fig. 19 Distribution of archaeological finds from basketry with wrapped twining structure on Argentine territory: pottery impressions and baskets

results show interactions among communities occupying a large area and grounded on long-time relationships. It also challenged the idea of a “cultural borderline,” a theoretical construct which has been frequently applied to the role played by the Western Lowlands in the regional processes and links taking place in the Andean area.

Additionally, we propose that basketry would have been integrated into the rest of the technological-production activities of the communities by participating in pottery manufacture (Fig. 22).

Due to a high proportion of impressions on the pot's base, it has been determined that basketry artifacts – most of them with evidence of intense use and damage – could have been used to support the pot during modeling and/or drying. Examples of this practice are found in ethnographic data from northeastern and northwestern Argentina, which depicts the use of textiles by

local indigenous populations as a support during pottery making (Boman, 1908/1991; Gardner, 1919; Outes, 1909). Moreover, the absence of standardization or homogeneity in the constructive attributes of the materials used as the support suggests a household production of both pottery and basketry inside domestic units, as the ones documented earlier (Millán de Palavecino, 1958–1959).

It is interesting to wonder why the impressions are limited to a relatively reduced number of bases in the total assemblage of local pottery. Were they obliterated in the remaining pots? Or was basketry used as a support for some specific pieces, perhaps aimed at concrete functions and/or contexts? In an attempt to find the reason, we suggest that contextual data indicate that the pieces with impressions had a funerary use. They refer to large vessels used as funerary urns or containers and some smaller pieces, such as deep and shallow bowls (pucos and escudillas)

Basketry of South America, Fig. 20 Findings related to the wrapped twining structure on Argentine territory: (a) plasticine casts of basketry imprints in pottery from sites in Córdoba and La Rioja (Serrano, 1945, p. 221); (b) basket printed on a piece of pottery from El Bañado, Quilmes, Tucumán (Boman, 1908/1991, Lámina II, figura 3); (c) basket recovered in a funeral context of Antofagasta de La Sierra, Catamarca (Ambrosetti, 1904, lámina

III); (d) specimen from Quebrada de Las Cañas, Quilmes, Tucumán (Liberani & Hernández, 1877/1950, p. 118); (e) one of the two baskets recovered in Loro Huasi, Tinogasta, Catamarca (Pérez de Micou, 2000, p. 106) y; and (f) pieces recovered at the Medanos site, Tinogasta, Catamarca (Department of Anthropology of the Province of Catamarca)

which were used as lids for the larger containers. In this respect, a link may be postulated between the funerary nature of these vessels and the presence of impressions.

Finally, we pave the way for future research of the esthetic aspects implied by the visual overlapping of both technologies (basketry and pottery) in the production, use, and/or circulation contexts of vessels. In other words, we are interested in the significance of the “overlapping” of both productions, where the basket is missing, but there are evident signs in its print, materialized as an impression on the pot’s surface.

We further highlight the relevance of carrying out the study of any kind of indirect evidence which may provide the information unavoidably lost with the original baskets, particularly in

areas where environmental conditions are not appropriate for the natural survival of organic materials. Thus, despite the impossibility of getting access to direct basketry records because of local weather conditions, lasting elements can greatly enlarge our knowledge about perishable materials.

Basketry of Brazil

So far basketry has not been a well-studied subject in Brazilian anthropology and archaeology. Most archeologists have spent more time trying to understand social variation through stones and pottery. Also Brazilian anthropologists were more interested in shamanic transformations

Basketry of South America, Fig. 21 Baskets (*tipas*) of current manufacture. Collection of the Department of Anthropology of the Province of Catamarca

rituals, for instance, than in objects like baskets. On the other hand, some researchers spent some time discussing the importance of symbols and contemporary baskets in indigenous societies, especially in the Amazon (Reichell-Dolmatoff, 1985; Silva & Gordon, 2011).

In different places in South America or even around the world, basketry is certainly one of the oldest native technologies. However, weather conditions in Brazil had almost caused the greatest loss of them in archaeological sites.

In the nineteenth century Debret illustrated some kinds of indigenous basketry (Fig. 23).

According to Souza (2010) in *Tratado Descritivo do Brasil* in 1587, in Brazil they found several types of fibers such as “timbós” and “timboranas,” used in handmade baskets and to tie woods that cover huts. Furthermore,

Jean de Lery reported a conical shaped tupinambá basket named “panacu.” “They were large and small baskets carefully woven in small canes, wicker or corn straw.” Panacus were included even in tupinambá imagery as the Jesuit priest Fernão Cardim (2009, p. 175) who wrote his account in the sixteenth century reported:

Sometimes rise up among them (Tupinambá people) some wizards, whom they called “Caraíba”, “Santo” or “Santidade”, and that usually occurred to an Indian with a bad life. He made a couple of witchcrafts, and did weird things to the nature, and was someone who resurrected people who had simulated being dead and other similar things (..) He said others should stop growing their vegetables and provisions, neither dig nor work, so on... Because after he arrived, it became the time that hoes would dig by themselves and also the panacus would go to the farm to bring the provisions by themselves.

Basketry of South America, Fig. 22 (a) Bowl with basketry impression on the base; (b) craftswoman ceramicist from Cañelo-Kitchwa (Ecuador), using a textile as a

support for pottery manufacture (Source: www.minelinks.com/ecuador/kichwa_es.html)

Basketry of South America, Fig. 23 Indigenous basketry illustrated by Debret

In the Handbook of South American Indians, the seminal book edited by Julian Steward, there are a couple of basketry mentions. About Southern Kaiapó, a Gêpeople who lived around

Parnaíba River near of Upper Araguaia, Lowie (1946, p. 519). Steward points out that cotton was neither cultivated nor spun. Textiles included mats and elliptical baskets of buriti fiber. Metraux

(1946a, p. 524), who describes the Purí-Coroado linguistic family, claims that:

The Coroado who raised some crops, had more elaborate cooking techniques and utensils [then purí], such as basketry sifters and various earthenware vessels. Besides, women carried their goods in large baskets.

According to Metraux, Coroado basketry did not differ from the more advanced Tupi tribes. They made rectangular fans to activate the fire, long-carrying baskets with open tops, and other containers of various sizes. About Caingang or Kaingang, Metraux (1946a, p. 457) claims:

[Their] carrying baskets had a hexagonal weave, and, like those of The Tupi, were elongated and rectangular knapsacks open on top and on the outer side. Basketry containers woven from thin strips of split bamboo frequently had stepped designs produced by alternating black and natural color strands.

The Aweikoma (Kaingang from Santa Catarina) “had three main types of baskets: large baskets for transportation of goods; small, impervious water or honey containers of taquaramansa strips coated with wax; and small receptacles, similarly waterproofed, used as cups and dishes” (Metraux, 1946, p. 457).

Currently, Reichell-Dolmatoff’s work shows something else beyond descriptions. He understands that Brazilian basketry has many values. There are material and technological aspects, but there are also certain sets of specific meanings which tend to emphasize spiritual factors above material ones (Reichell-Dolmatoff, 1985, p. 2). Through plaited trays and fishing traps decorations of the Desana people from northwest Amazon, on the Brazil-Columbia border, he shows how specific meanings can be conveyed.

According to Reichel-Dolmatoff their exogamic relationships laws were illustrated on basket decorations, to remind the people that they should never marry a person from the same tribe.

Following Binfordian’s theoretical approaches in an ethnoarchaeological paper, Silva (2011) proposes a situational perspective where the Xikrin people had two different kinds of baskets. There is a simpler one – “expedient” – handy and quickly made, equally

quickly disposed of, that does not carry or convey any symbolic message and can be made by anyone; the other is a more complex kind – “curated” – on which basketmakers spent much time and which is more important symbolically. These are different from Desana baskets, as they had two different categories: one was totally functional and the other was full of meanings. Both of them were made using the same raw materials and the same technique: twill plaited.

Ribeiro (1985, p. 12) noticed among the Kayabí Indians “symbolic representations of their basketry patterns that schematize human pictures like supernatural mythic beings and more significant plants or animals inside these Indians lifecycle.” Van Velthem (2007) demonstrated how several Wayanã and Apalai cosmological elements appeared on basket and mat iconography, crossing Euro-American art, myth, and technology concepts in only one object. The “mirikuit” motifs showed vegetables, animals, and “imaginary beings.” Van Velthen recognized that decoration in body paint is the same as that on basketry.

Ribeiro edited a remarkable inventory where a large part of Amazonian material arts were characterized. The illustrated *Dicionário do Artesanato Indígena* (1988) presents and explains basketry, pottery, cordage, and more work techniques beyond several schematic pictures. It is a fundamental book for those that are researching Brazilian basketry.

Archaeological basketry features are quoted by several authors (Dias junior, 1993; Martin, 2005; Lima, 1984, 1986, e 2012; Oliveira, 2001; Prous, 1992), but none made deep inquiries about this kind of material culture. They mostly noticed the beauty of these artifacts. Costa was the first to dedicate himself to this subject through his doctoral dissertation on development *Palha e Tala: A Tecnológico Trançado entre Grupos Pré-históricos Brasileiros*. Costa chose baskets, mats, and other perishables from four sites where basketry was recovered and where there was at least some information about their contexts. Impressions on pottery were merely considered.

Material from each site has special characteristics, though most of them are associated with

Basketry of South America,

Fig. 24 Fragment of mat from Alcobaça site

B

burial rituals. Costa decided to work with Adovasio's methodology and terminology classifying the artifacts and establishing cultural borders among each particular region or site. As there are still no conclusions to his work, we show some comments for each assemblage. All analyses were conducted in R.L Andrews Basket Center, Mercyhurst Archaeological Institute under Jeff Illingworth's support.

Alcobaça site is a sandstone rock-shelter full of Agreste horizon paintings located in North-eastern Pernambuco. Excavation was carried out from 1996 to 1998. Five fire pits were found there; one of them had remains of basketry dated to 1.118 ± 24 B.P. At least 23 individuals were buried in this area. Seven samples were selected for technological analysis (1977); most of them were open simple twined with Z or S twist (5) and 2 of them were open and simple twined. The raw material was not identified, but probably was caroá (*Neoglaziovia variegata*) or some types of palms like ouricuri (*Scheelea Phalerata*) and babaçu (*Attalea* ssp.) and coconuts. Forms related to these features were almost never identified, except for some of them which were similar to mats (Fig. 24). The Alcobaça site is the only site where basketry remains found were not associated with funeral contexts.

Furna do Estrago is also in the state of Pernambuco, Brejo da Madre de Deus municipality.

This site was occupied during several periods between 11,000 and 1,040 B.P. and it is a 120 square meters rock-shelter. At least 80 individuals were buried there. According to Lima (2012) the site must have been used as a cemetery for about 250 or 300 years. Basketry certainly was present in most burials. Sometimes the person was left above a kind of fiber later replaced by mats. Also they usually put caps on the corpse's skull (Fig. 25). Thirteen fragments have been analyzed including several fragments of knots. Simple plaiting and open twining with Z twisted were the most common techniques used. Raw materials were possibly similar to the Alcobaça ones.

In Minas Gerais State, there are two other sites where basketry remains have been found. Gruta do Gentio is a limestone cave measuring 2.5 km. A mummified toddler was found there. He was wrapped in deer flesh straps and fabrics. Also there were other burials in Gentio (Dias junior, 1993). According to Dias Junior, the researcher who directed all the excavations at this site, all the perishables were found in the first layer dated from 1,000 to 3,500 B.P. The most interesting sample was a 3/3 twill plaiting with a 4 strand braid cord attached to it as a carrying strap. It was constructed by taking two palm fronds and weaving the leaves together. Costa has supposed that it is similar to the one named by Ribeiro (1988) "cestobornaliforme" used until today by the

Basketry of South

America, Fig. 25 Cap on the Furna do Estrago corpse's skull (From: <http://institutoanchietanodepesquisas.blogspot.com/2012/11/pesquisas-antropologia-n-69-furna-do.html>)

**Basketry of South**

America, Fig. 26 Plaited fragments (3/3) from Gruta do Gentio (Gentio Cave). Photos by: Rodrigo Lessa

Xavante people. It could be also a manioc process tool.

The other significant site where perishables were founded is in Minas Gerais State, in "Lapa

do Boquete." Boquete was used as a cemetery, but there were also food storage structures named "silos." Mats and other straw structures were covering and splitting these silos in several

levels. They also found a mummified individual with bones, skin and even hair attached to the bones, and several plant fiber artifacts. It was dated to 560 ± 40 BP, and as the one at Furna do Estrago, the corpse's skull was surrounded by straw like a cap. A large 2/3/2 twill plaited was a very interesting artifact associated with this burial, not just because of technical or decorative elements but because of the context where it was found. Prous and Schlobach (1997) affirmed that this basket was *nécessaire* [necessary] to life after death. Inside the basket there were polished awls, shell tools, a wax ball, a small gourd with a silex flint with red color residues inside, a deer tooth, and three other gourds, one of them with basketry wrap attached, also 2/3/2 twill plaited (Fig. 26).

Studies on Brazilian basketry are just beginning, so we cannot claim what will be the direction of social questions. Some technical points can be quoted. Coiled baskets were not included in Brazilian prehistoric basketmakers' technical set. They preferred weave-plaited objects, though twining appeared especially in Furna do Estrago and Alcobaça, which could denote a regional preference. Also relationships among people who lived in these two sites could be looked into through basketry elements. Decorations were extremely rare, except for red pigment remains on a single-plaited mat from Furna do Estrago. However, it is hard to explain anything about decorations – especially paintings – because of conservation problems that we already mentioned.

Basketry of the Wabanaki Indians

Jennifer S. Neptune¹ and Lisa K. Neuman²

¹Maine Indian Basketmakers Alliance, Indian Island, ME, USA

²The University of Maine, Orono, ME, USA

The Wabanaki

The Wabanaki (People of the Dawn Land) are living Algonquian-speaking indigenous Native North Americans whose traditional homelands comprise what is today northern New England in the United States as well as Southeastern Quebec and the Canadian maritime provinces of New Brunswick, Nova Scotia, and Prince Edward Island. In the United States, there are five federally recognized Wabanaki tribes, all of which

reside in the state of Maine: the Penobscot Nation (with a reservation in Penobscot County, Maine), the Passamaquoddy Tribe at Pleasant Point or Sipayik (with a reservation in Washington County, Maine), the Passamaquoddy Tribe at Indian Township (also with a reservation in Washington County, Maine), the Houlton Band of Maliseet (in Aroostook County, Maine), and the Aroostook Band of Micmac (also in Aroostook County, Maine). The Wabanaki also own trust lands (property with federal status owned by the tribe or tribal members) and fee lands (taxable property owned by tribal members but for which a tribe regulates use) in other parts of the state of Maine (Fig. 1). As of 2014, there were approximately 8,000 people on the membership rolls of the five Wabanaki tribes in Maine, with a far greater number in Canada.

A note here on terminology is important to avoid confusion. Today there are groups of people in Northern New England and Canada called “Abenaki,” historically a part of the larger Wabanaki Confederacy of Algonquian-speaking groups. In discussing basket making, we focus on the five federally recognized Wabanaki tribes now residing in Maine (as well as their kindred in Passamaquoddy, Mi’kmaq, and Malecite communities in Canada), not the US or Canadian Abenaki. Note that all groups have alternate spellings and pronunciations, including those that differ across the US-Canada border (e.g., Micmac or Mi’kmaq, Maliseet or Malecite). We will use Anglicized spellings that are in use and commonly accepted today in Maine. We will also use the terms “Indian,” “Native American,” “Native,” and “indigenous” interchangeably in referring to the Wabanaki people more generally.

History of Wabanaki Basketry

While historically Wabanaki baskets have been made from a variety of materials including birch, basswood, maple, spruce, and cedar, it is brown ash – also known as black ash (*Fraxinus nigra*) (Fig. 2) – that figures most prominently in Wabanaki basketry today. The place of ash basketry in Wabanaki life runs deep, as far into the

past as collective memory can recount the story of how Gloosekap (alternately spelled Glooskap, Gluskabe, Gloosecap, Glooscap, or Klooskap) shot his arrows into the ash trees to create the Wabanaki people. Prior to European contact, the Wabanaki people in Maine were hunters and gatherers, who moved seasonally and utilized bark, wood, and tree roots from the forests along with aromatic sweetgrass and cattails from the coastal wetlands to craft utilitarian bags, boxes, and other containers (McBride & Prins, 1990). The Wabanaki people also utilized types of woven baskets for washing corn, sifting, and carrying supplies. Some evidence suggests that the arrival of Europeans and their roles as trading partners may have accelerated Wabanaki production of splint basketry – that is, baskets produced using thin uniform strips of wood braided or woven together – from forest resources like ash, cedar, spruce, and maple (McBride & Prins, 1990). It is clear that splint basketry – especially that constructed from the versatile brown ash – is central to Wabanaki cultural and spiritual life.

Historically a skill passed down within families, basket making took on new economic, cultural, and social meanings for Wabanaki communities beginning in the eighteenth century, as traders, tourists, museums, and basket makers helped shape a consumer market for Wabanaki baskets (Bourque & Labar, 2009). As non-Native vendors and collectors sought out Wabanaki baskets as consumer goods of artistic value, indigenous basket makers traveled to major cities like Boston, New York, and Philadelphia along the Eastern seaboard to sell their products (Neptune, 2008a). Beginning in the mid-nineteenth century, Wabanaki families set up encampments in well-known resort towns such as Kennebunkport and Bar Harbor on Mt. Desert Island, Maine, to sell their baskets and other crafts to wealthy summer residents and vacationers (McBride & Prins, 2009). New styles of ornamentation and decorative weaves accompanied the introduction in the 1860s of labor-saving commercial aniline dyes, which allowed for a brighter and more varied basket color pallet (Neptune, 2008b; Whitehead, 2004). By the mid-1880s, new technologies

Basketry of the Wabanaki Indians, Fig. 1 Map of Wabanaki territory. Showing tribal reservations, trust, and fee lands in Maine (Courtesy of James Eric Francis, Sr.)

improved the manufacturing of tools like wood splitters, gauges, and blocks for holding a basket's shape, which helped Wabanaki basket

makers create even smaller and fancier decorative baskets (Mundell, 2008). For example, Penobscot men who worked at canoe factories

Basketry of the Wabanaki Indians, Fig. 2 Black ash trees. They can grow 60–70 f. in height and reach a trunk diameter of 8–24 in., producing a small cluster of branches high off the ground (Courtesy of Jennifer Neptune)

in Old Town, Maine, used factory lathes to create new shapes and styles of basket blocks. By the turn of the twentieth century, tribal census data reveal that almost every Passamaquoddy and Penobscot household had at least one member whose primary occupation was basket maker. Making baskets was a communal and intergenerational activity (Figs. 3 and 4). Women would often host sweetgrass braiding parties in their homes, and children could observe the work of adults and sometimes make their own miniature baskets.

During the twentieth century, several historical events profoundly affected Wabanaki basket makers. A decline in tourism due to the Great Depression and the onset of World War II (in which many Wabanaki men and women served) and postwar Wabanaki migration to southern New England (spurred by new job opportunities and the desire to escape racial prejudice back home) led to a decline in the number of Wabanaki basket makers during the middle

part of the twentieth century. From the 1950s to the 1980s, competition from foreign imports and the development of plastic containers, coupled with changes in the potato and fishing industries that led to less demand for Wabanaki utility baskets, promoted further decline in the number of basket makers. Moreover, during this time period, coastal development and changes in land use restricted Wabanaki access to traditional ash and sweetgrass gathering and selling sites. The northern extension of the interstate highway system I-95 during the 1960s diverted traffic away from the Penobscot reservation in Old Town, Maine, taking with it potential customers for basket makers. By the 1990s, it is estimated that there were fewer than one dozen Wabanaki basket makers left under the age of 40 (Neptune, 2008b).

In 1993, Wabanaki basket makers created the nonprofit Maine Indian Basketmakers Alliance (MIBA) to help market their baskets, educate the public about tribal issues, revitalize aspects of traditional Wabanaki languages and cultures, and pass on basket-making skills to younger generations through apprenticeships with elder basket makers. Wabanaki basket makers have written a number of books about Wabanaki basketry, including the styles of Penobscot, Passamaquoddy, Micmac, and Maliseet basket makers (see Sanipass, 1990; Soctomah, 2003; Nichols, Francis, Francis, & Soctomah, 2008). Basket makers display and sell their baskets at a number of venues, including the Abbe Museum in Bar Harbor, Maine, as well as seasonal basket shows at locations around the state of Maine, which also provide opportunities for extended families and friends to socialize (Neuman, 2010). Wabanaki basket makers also have a presence in larger international Native American arts markets, such as Santa Fe Indian Market, with weavers receiving first place and best of show ribbons. Today, museum-quality Wabanaki baskets made by well-known basket makers can fetch as much as a few thousand dollars apiece – a far cry from the pocket change that early twentieth-century tourists would often pay for baskets. For most weavers, basket making provides a modest income and may supplement

other forms of employment. Moreover, for many Wabanaki people, basket making signifies a process of decolonization, as the production of baskets is inseparable from assertions of tribal/band sovereignty, land use rights, and indigenous identities in twenty-first-century America and Canada (Sockbeson, 2009). However, Wabanaki basket makers face new twenty-first-century threats, including co-optation of their intellectual property rights by non-Wabanaki people, restrictions on access to their traditional brown ash and sweet-grass harvesting sites, and an invasive species of ash-destroying beetle: the Emerald Ash Borer (*Agilus planipennis*) (Fig. 5).

Procuring and Preparing Materials

Brown ash possesses unique characteristics that make it an ideal material for making baskets. Brown ash is strong enough that it can be woven into sturdy utility baskets, yet it is flexible enough to be woven into highly detailed, intricate, and delicate ornamental baskets, known as “fancy” baskets. Its growth rings can be pounded and split into fine splints that are ideal for weaving. However, not all brown ash trees – which tend to grow in wet areas – make good basket trees. Basket makers who harvest brown ash carefully select individual trees based on a set of complex

Basketry of the Wabanaki Indians, Fig. 5 Emerald Ash Borer emerging from an ash tree (Photo by Jennifer Neptune. Courtesy of Maine Indian Basketmakers Alliance)

technical criteria for matching individual trees to their basket-making needs. For example, by notching a small section of the trunk with an axe, a harvester can tell yearly tree ring growth and its suitability for a utility or fancy basket.

Once an ideal basket tree has been identified, it is cut into lengths of 4–12 ft. A spiritual offering may be given at the time a tree is cut. After removing the bark, harvesters use the blunt side of an axe to pound down the length of the log, which separates and releases the growth rings into layers. This produces long straight splints of 4–12 ft in length. As the ash is being pounded, the splints may be split into thinner segments using a splitter (Fig. 6).

Once a growth ring is divided into two parts, it may be split into even finer segments that can be paper thin in some cases. Splitting the ash creates new thinner segments that contain the original rough sides and new smooth surfaces. The rough sides may be smoothed with a knife in a process called scraping. The smooth thinner segments are ideal for delicate fancy baskets. At that point, the splints can be coiled and stored for later or they can be pulled through a sharp-toothed instrument called a gauge (Fig. 7), which cuts them into the desired widths.

Along with brown ash splints, basket makers harvest a highly aromatic marsh-loving grass called sweetgrass, which is integrated into the weave. In addition to being highly prized as a

Basketry of the Wabanaki Indians, Fig. 6 Splitting black ash splints with a wooden tool known as a splitter (Photo by Jennifer Neptune)

weaving material, sweetgrass plays an important role in spiritual and cultural practices (Fig. 8). Sweetgrass became more prominent in fancy baskets during the mid-nineteenth century, as Wabanaki traditional summer village sites on the Maine coast began to overlap with the growth of summer resorts and a new tourist market for baskets.

Weaving Baskets

Now the weaving process begins. Wide splints (called standards) are woven to form the base of the basket, and smaller splints that have been gauged into narrower widths (called weavers) are woven to form the sides and the bottom of the basket. Many basket makers use a wooden form called a block, which is tied to the base to help shape the sides as they are being constructed. After the sides have been woven, the block is then removed. The rim of the basket is then bound by

Basketry of the Wabanaki Indians, Fig. 7 Gauge for cutting splints (Photo by Jennifer Neptune)

Basketry of the Wabanaki Indians, Fig. 8 Picking sweetgrass for weaving (Photo by Jennifer Neptune)

tucking in the standards and finishing the rim's edge with materials, like sweetgrass, that strengthen it and add a decorative touch. Basket makers may weave covers or carve handles for their baskets.

There are two major categories of Wabanaki baskets: utility baskets and fancy baskets. Heavier and sturdier utility baskets are generally

used for gathering, transporting, processing, and storing food and other items. Two of the most recognizable styles of utility basket are the pack basket (often used in canoes) and the potato basket, which was essential for agriculture in Maine. Function, and not ornamentation, governs the production of utility baskets (Fig. 9).

On the other hand, fancy baskets are defined by and sought after for their ornamentation. Weavers will manipulate the ash into curls, twists, and points. Brightly colored and sometimes whimsical fancy baskets in the shapes of foods like blueberries, strawberries, pumpkins, pinecones, and corn are a hallmark of the Wabanaki style of basketry (Fig. 10).

Economic, Environmental, Social, and Cultural Dimensions of Wabanaki Basketry Today

The Maine Indian Basketmakers Alliance has succeeded in bringing together the technical knowledge and specialized skills of various basket makers into one organization dedicated to the preservation of the craft. The MIBA's program of pairing master basket makers with apprentices, with the explicit goal of preserving traditional knowledge (including Wabanaki language) and increasing the number of younger basket weavers, has been extremely successful. Today, there are approximately 200 Wabanaki basket makers in Maine. The MIBA has also been successful in marketing Wabanaki basketry and promoting its status as an art form among collectors; this also has helped raise consumer demand and prices for baskets.

Yet, Wabanaki basket makers in the twenty-first century face several threats. Access to traditional ash and sweetgrass gathering spots has been diminished due to coastal development, changing landowner attitudes concerning access, and new regulations imposed by large-scale landowners such as paper companies. Basket makers also must contend with infringement on their intellectual property rights: some businesses and individuals copy their unique styles and attempt to sell baskets as "Wabanaki" that are not made

Basketry of the Wabanaki Indians,

Fig. 9 Utility baskets by Peter Neptune (Passamaquoddy)
(Courtesy of Maine Indian Basketmakers Alliance)

Basketry of the Wabanaki Indians, Fig. 10 Fancy baskets by Passamaquoddy weavers Clara Keezer and Theresa Gardner (Photo by Jennifer Neptune)

by Penobscot, Passamaquoddy, Micmac, or Maliseet artisans. It is no wonder that many basket makers link their practice of making baskets to cultural survival and decolonization – that is, their continuing struggle against the effects of encroachment on their lands and traditions by outsiders.

However, perhaps the most pressing issue for Wabanaki basket makers today is the environmental threat posed by an invasive insect known as the Emerald Ash Borer. Discovered in 2002 in Michigan, the Emerald Ash Borer is believed to have traveled to North America on shipping pallets from Asia. This small beetle kills all species of ash trees and has destroyed millions of trees

since its arrival. Adult beetles lay their eggs on the bark of the tree, and the hatching larvae bore into the tree to feed on the inner bark. As the larvae feed, they create “S”-shaped galleries, which eventually girdle the tree, effectively killing the tree from the inside out. Infestations can be hard to detect, as symptoms often are not visible for three or more years. The Emerald Ash Borer has rapidly spread from the Great Lakes region of the United States to other areas, moving into the central, southern, and eastern United States as well as the Canadian provinces of Ontario and Quebec. Emerald Ash Borer on its own would spread over the landscape fairly slowly; however, humans have accelerated its spread by transporting infected firewood, logs, and nursery stock hundreds and sometimes thousands of miles. While natural predators help keep the Emerald Ash Borer in check in Asia, it has no natural enemies here. Left unchecked, it threatens to destroy virtually all of the ash trees in North America.

The Future of Wabanaki Basketry

Basket makers have adopted a number of proactive strategies to ensure the future of Wabanaki basketry. Since 2010, Maine has banned the importation and transportation of firewood into Maine from other states. Wabanaki basket makers and Wabanaki scholars testified before

the Maine Legislature and played a major role in the enactment of this legislation. Wabanaki basket makers – along with policymakers, forest service employees, and scholars from around the country – have formed black ash task forces to prepare for the arrival of the beetle, held symposia dedicated to preserving and sharing vital information about ash trees, and collaborated on cross-country field trips to learn how to identify the Emerald Ash Borer, to recognize damage and signs of the beetle, and to share strategies and knowledge about coping with the damage that will be caused by the beetle. Basket makers and conservationists are also saving seeds to preserve the ash trees for future generations.

Cultural knowledge is being preserved as well. Wabanaki ash harvesters are creating filmed records of tree identification, processing, and basket making so that this knowledge can be archived for future generations of Wabanaki basket makers. Some Wabanaki basket makers are also diversifying the materials they are using to craft baskets, returning to other traditional materials like basswood, birch, maple, and cedar, which are protected from the threat of the Emerald Ash Borer. In 2013, the Maine Indian Basketmakers Alliance, the Penobscot Nation, and the Bangor Museum and History Center pooled their resources to purchase a rare woven antique Penobscot basswood bag from an estate auction. Now housed at the Hudson Museum at the University of Maine, this basswood bag has the potential to inspire future generations of Wabanaki basket makers.

Baudhāyana

R. C. Gupta

India's most ancient written works are the four *Vedas*, namely *R̥gveda*, *Yajur-veda*, *Sāma-veda*, and the *Atharva-veda*. There are different schools which are represented by various *Śaṃhitās* or recensions of the *Vedas*. To assist their proper study, there are six *Vedāṅgas* (limbs or part of the *Veda*), namely *Śikṣā* (phonetics), *Kalpa* (ritualistics), *Vyākaraṇa* (grammar), *Nirukta* (etymology), *Chandas* (prosody and metrics), and *Jyotiṣa* (astronomy, including mathematics and astrology). These auxiliary Vedic works (except the last) are written in *sūtra* or aphoristic style.

The *Kalpa Sūtras* deal with the rules and methods for performing Vedic rituals, sacrifices,

and ceremonies, and are divided into three categories: *Śrauta*, *Grhya*, and *Dharma*. The *Śrauta Sūtras* are more specifically concerned with the sacrificial ritual and allied ecclesiastical matters. They often include tracts which give rules concerning the measurements and constructions of *agnis* (fireplaces), *citis* (mounds or altars), and *vedis* (sacrificial grounds). Such tracts are also found as separate works and are called *Śulba Sūtras* or *Śulbas*. They are the oldest geometrical treatises which represent in coded form the much older and traditional Indian mathematics. The root *śulb* (or *śulv*) means “to measure” or “to mete out”.

The names of about a dozen *Śulba Sūtras* are known. The oldest of them is the *Baudhāyana Śulba Sūtra*. It belongs to the *Taittirīya Samhitā* of the *Black Yajur-veda* and is the 13 *Praśna* or chapter of the *Baudhāyana Śrauta Sūtra*. The title *Baudhāyana Śulba Sūtra* shows that its author or compiler was Baudhāyana, or perhaps more correctly, it belonged to the school of Baudhāyana. Other Vedic works bearing the same name are known. It is more proper to consider these works as belonging to the Baudhāyana school than to regard them as authored by the same person.

Here we are concerned with Baudhāyana the *śulbakāra* that is, the author of the *Baudhāyana Śulba Sūtra* or the *sulbavid* (expert in *sulba* mathematics and constructions). We do not know his biographical details. Georg Bühler believed that he hailed from the Andhra region, but a recent study by Ram Gopal shows that he probably came from northern India. His dates are also uncertain, being any time between 800 and 400 BCE. Taking into account the views of A. B. Keith, W. Caland, David Pingree, and Ram Gopal, he may be placed about 500 BCE or earlier. However, it must be noted that much of the material in *Baudhāyana Śulba Sūtra* is traditional and, thus, still older than its date of compilation and coding.

The *Baudhāyana Śulba Sūtra* is not only the earliest but also the most extensive among the *Śulbas*. The subject matter is presented in a systematic and logical manner. Of course, the language is somewhat archaic, and due to the

aphoristic style, the rules are highly condensed. The *Baudhāyana Śulba Sūtra* was commented on by Dvārakānātha Yajva (ca. seventeenth century). His Sanskrit commentary called the *Śulbadīpikā* was published more than a century ago by Thibaut (1848–1914) in his edition of the *Baudhāyana Śulba Sūtra*. A recent edition (Varanasi 1979) of the *Baudhāyana Śulba Sūtra* also contains the above commentary as well as another called *Bodhāyana śulbamīmāṃsā*, which was written by Vyāṅkateśvara (or Veṅkateśvara) Dīkṣita who lived during the Vijaya-nagaram kingdom (ca. 1600).

The text of the *Baudhāyana Śulba Sūtra* is divided into three chapters which comprise a total of 272 passages or 519 aphorisms. The main subject is the measurement, construction, and transformation of various altars and fireplaces. The forms of the three obligatory *agnis* (whose tradition was older than even the *pgveda*) were square, circle, and semicircle, but those of optional *citis* involved all sorts of plane figures, including the above three and also the rectangle, rhombus, triangle, trapezium, pentagon, and some complicated shapes.

Some mathematical topics covered in the *Baudhāyana Śulba Sūtra* are a fine approximation for the square root of two and the so-called Pythagorean theorem. In the latter, the sides of a right-angled triangle obey the rule $a^2 + b^2 = c^2$.

The *Baudhāyana Śulba Sūtra* also contains formulas for circling a square and squaring a circle, and provides rules for basic simple geometric constructions, such as drawing a perpendicular on a given line or drawing the right bisection of a line. Some other elementary plane figures such as the isosceles triangle, trapezium, and rhombus are also covered for construction.

The *Baudhāyana Śulba Sūtra* deals with the measurements and constructions of a large number of fire-altars (*Kāmya agnis*). These were needed as part of rituals performed to attain certain desired objects according to the religious beliefs of the Vedic people. It was essential that the shape, size, area, and orientation of the relevant altar be according to the prescribed instructions. Otherwise, there was a risk of divine wrath.

The standard forms of some of the optional altars were those which resembled certain birds. The most significant and perhaps the oldest of such altars was the *śyenaciti* (falcon-shaped altar). It was to be constructed when one desired heaven (after death) because “the falcon is the best flyer among the birds.” The spatial dimensions, the number of bricks (of prescribed shapes and sizes), the number of layers, etc., are all given. It is interesting to note that the archaeological remains of this most striking and complicated *śyenaciti* reported to be built in Kausambi in the second century BCE, still survive.

Early Indian geometry developed because of the need for accurate altar constructions and transformations which often required quite advanced mathematical knowledge.

Beads

Tom Holland¹, Sage Holland¹ and Robert Bednarik²

¹Meadowcreek, AR, USA

²International Federation of Rock Art Organizations (IFRAO), Caulfield South, Australia

Of the Paleolithic forms of possible symbolic products, beads and pendants seem to tell us the most about the cognition and technology of their users. First, there are the purely technological aspects. To make a bead, one has to be able to drill through an object (or enlarge a natural perforation), thread a string through the hole, and fasten the ends of the string, presumably by knots (Warner & Bednarik, 1996). To persist with such a process of manufacture, one must have a mental construct of the end product and a desire to acquire what is clearly a non-utilitarian artifact. While the bead is such an artifact, the string is not, being utilitarian. It is merely a means of permitting the bead to fulfill its non-utilitarian role. Hence, this is a combination not only of diverse (composite) and interactive artifacts but also a hierarchy of diverse concepts of relating to them. The primary imperative, presumably, is to display the bead to its best advantage; the secondary intent is to find a means of doing so. A piece of, say, ostrich eggshell can be worn on a string without first drilling a hole through it, so why bother with this additional work? It is through such considerations that beads are imbued with the potential of meaning and significance.

Whether they are sewn on apparel or worn on strings, beads, and pendants has symbolic meanings that are far removed from the empiricism of

the interpreting Western anthropologist. For instance, they may be protective, warding off evil spirits or spells, or they can be good luck charms. They can signify status (e.g., availability for marriage, political status, and state of mourning) and convey complex social, economic, emblematic, cultural, ideological, religious, or ethnic meanings or any subtle combinations of them. Their emic meanings can be public or private, but they may be difficult to convey to an alien researcher, and they could never be deduced reliably through archaeology.

Beads have no possible utilitarian function that is not attributable to purely symbolic purposes. Describing them as decorative, for instance, does not amount to any clarification, because it does not tell us why they are “decorative.” All communicative functions of beads are culturally negotiated; the abstract values they communicate to the initiated beholder are crucial to their existence, yet for the early periods of humanity they are entirely inaccessible to the researcher. The outstanding technical perfection of some particularly early specimens has prompted the proposition that these objects expressed concepts of perfection, and it has been demonstrated, via replicative experiments, that such perfection was achieved through a great investment of labor and carefully applied skills (Bednarik, 1997). The intentionality of perfection as well as the various layers of intended cultural meanings of such objects would have been all impossible without the use of a “reflective” communication system of a complexity that does not seem achievable without consciously modulated speech. Hence, beads and pendants constitute key evidence in the quest to clarify the cognitive evolution of humans – not just because they demonstrate the use of symbolisms, but because they demand social, cultural, and cognitive systems of an adequate sophistication to support the complex aggregate of mental abstractions without which such objects simply cannot exist. We have many other indicators of language use several hundred thousand years ago, during the Lower and Middle Paleolithic (e.g., other forms of symbolism or seafaring), but the use of beads and pendants during these earliest phases of

human culture provides one of the most crucial forms of such evidence.

Middle and Lower Paleolithic finds with both artificial and natural perforations are quite common, and many hundreds have been found since the mid-nineteenth century. They demonstrate considerable complexity of human cognition and social structures up to perhaps half a million years ago. The earliest mention of possible beads of the Lower Paleolithic relates to the first Paleolithic tools ever reported, from the very type site of the Acheulian (Boucher de Perthes, 1846). Prestwich (1859, p. 52), who recognized the authenticity of the St. Acheul stone tools Jacques Boucher de Perthes had been collecting for many years, noted that the holes in some of the *Porosphaera globularis* beads he himself collected at French sites had been artificially enlarged. Similarly, many of the 200 Acheulian beads Smith (1894, pp. 272–276) discovered at Bedford, England, showed artificial enlargement of the natural orifice. These, too, were of *Porosphaera globularis* fossil casts, but Smith was not aware of the earlier French finds. His opinion that the globular fossils had been used as beads was confirmed by Keeley (1980, p. 164) who examined some of the Bedford specimens. However, these important finds remained largely ignored until Bednarik, interested in resolving the issue of the earliest beads, conducted a detailed microscopic study of 325 *Porosphaera globularis* specimens held in the Pitt Rivers Museum at Oxford University (Bednarik, 2005). They had all been collected before the early twentieth century, most in England, some in France. In focusing on the best provenanced part of the collection, the Acheulian finds from the Biddenham quarry at Bedford, he found that many specimens bore distinctive artificial flaking around the narrow end of the natural central tunnel. Moreover, many were observed to bear distinctive wear facets around both tunnel openings, which leaves no doubt about their use as beads. They must have been permanently arranged with their tunnels in alignment to acquire this wear – in other words, they must have been on a string and worn in that way for considerable periods, often for years (Fig. 1).

Beads, Fig. 1 Some of the Acheulian stone beads from Bedford, England (Photo by author)

Beads, Fig. 2 The technical perfection of ostrich eggshell beads, such as the El Greifa specimens, illustrates the cultural complexity of the Acheulian period (Photo by author)

Circular, disc-like fossil casts have also been found at Acheulian sites, such as the crinoid columnar segments (*Millericrinus* sp.) from Gesher Benot Ya'aqov, Israel (Goren-Inbar, Lewy, & Kislev, 1991), and in France columnar crinoid segments from a site on the Loire and from Soissons, near Aisne, Picardie (Bednarik, 2005). Several disc beads made from ostrich eggshell have been excavated from substantial Acheulian layers in Libya (Bednarik, 1997). They are from the El Greifa site complex at Wadi el Adjal, near Ubari. The site is located on what was a peninsula of the huge Fezzan Lake in the Pleistocene, which then occupied a large part of southwestern Libya. The U/Th isotopes of the calcareous sediments dated the ostrich eggshell beads from the Late Acheulian of El Greifa site E as being in the order of 200,000 years old. The near-perfect rounded circumference and central perforation of these beads demonstrate that hominins of the Acheulian possessed the

technology of working this fragile medium with confidence and skill. These perfectly made artifacts also imply the existence of the social structures necessary to provide an ideological context for the production and use of body "decoration" (Fig. 2).

Among the earliest objects with human-made perforations we know of are the two perforated pendants from the Repolust Cave in Styria, Austria. One is a wolf incisor, very expertly drilled near its root; the second is a flaked bone point, roughly triangular and perforated near one corner (Bednarik, 1997). Both objects have received little attention since they were first reported (Mottl, 1951). They were excavated with a lithic industry variously described as Levalloisian, Tayacian, and Clactonian, which is in fact an undifferentiated Lower Paleolithic assemblage, clearly free of Mousterian elements. There is no reliable dating evidence available; the currently favored age estimate of around 300,000 years is

Beads, Fig. 3 Perforated wolf incisor, Repolust Cave, Austria, probably of the Lower Paleolithic (Photo by author)

B

based on the accompanying faunal remains, especially the phylogeny of the bear remains (Fig. 3).

In addition to these Lower Paleolithic beads from three continents, there are numerous perforated objects also from the Middle Paleolithic, and many of them may have served as beads or pendants. The Micoquian has yielded an artificially perforated wolf metapodium as well as a wolf vertebra from the Bocksteinschmiede, Germany (Marshack, 1991; Narr, 1951), while the Micoquian of Prolom 2, Crimea, produced no less than 111 perforated animal phalanges, besides four engraved paleoart objects (Stepanchuk, 1993). The Mousterian of France has yielded a partly perforated fox canine and a perforated reindeer phalange and partly perforated fox canine from La Quina (Marshack, 1991; Martin, 1907–1910), another perforated bone fragment from Pech de l’Azé (Bordes, 1969), and a probable crinoid fossil from Fontmaure (van der Made, 2002). (A crinoid is a type of primitive marine invertebrate animal (echinoderm) with a cup-shaped body and five feathery radiating arms.) Perforated phalanges and perforated cranial fragment from Lezetxiki, Spain, are also of the Mousterian (Baldeon, 1993). Two perforated canines from Bacho Kiro, Bulgaria, too, are of the Middle Paleolithic (Marshack, 1991). The Middle Stone Age of Blombos Cave, South Africa, produced 41 perforated snail shells that are about 75,000 years old. Two slightly older perforated seashells come from Border Cave, also in South Africa (Beaumont, Miller, & Vogel, 1992), as does a centrally perforated ostrich eggshell fragment

from the same site, about 76,000 years old (Grün and Beaumont, 2001). Of similar age is a broken circular ostrich eggshell pendant from the Cave of Hearths (Grün and Beaumont, 2001; Mason, 1998). Other African finds of the general period are a perforated shell from Oued Djebanna, Algeria; four deliberately drilled quartzite flakes from Debenath, Nigeria; perforated marine shells with traces of red pigment from Grotte des Pigeons, Morocco, about 82,000 years old (Bouzouggar, Barton, & Vanhaeren, 2007); and a bone pendant from Grotte Zouhra, also in Morocco (McBrearty & Brooks, 2000). Toward the end of this technological phase, beads and pendants became increasingly common, and materials of stone began to be drilled, first appearing in Russia and China. Thirteen such specimens from the lower occupation layer of Kostenki 17, found below a volcanic horizon thought to be about 40,000 years old (from the Campanian Ignimbrite eruption in Italy), include not only polar fox canines (Fig. 4) and gastropod shells with perforations, but also stone and fossil cast objects (Bednarik, 1995). From an intermediate Middle to Upper Paleolithic site in China, wenhua Shiyu, comes a broken stone pendant (Bednarik & Yuzhu, 1991; Fig. 5). The oldest beads found in Australia, from Mandu Mandu Creek rock-shelter, are about 32,000 years old and of a stone tool industry of Middle Paleolithic technology (Morse 1993).

With the advent of the Upper Paleolithic in Eurasia, beads became more numerous in various regions. This includes specimens made by the Neanderthals of the Châtelperronian of the

Beads, Fig. 4 Beads and pendants from Kostenki 17, Russia, >40,000 years old. (a–c) are snail shells; (d–g) are silicified, semitranslucent fossils; (h–j) are fox canines; and (k–m) are stone pendants (Photo by author)

Beads, Fig. 5 Fragment of drilled stone pendant, about 28,000 years old, from wenhua Shiyu, China (Drawn by author)

French Upper Paleolithic, among them again a crinoid fossil segment (Leroi-Gourhan, 1965; Fig. 6). Just three graves at the Russian site Sungir – with a stone tool technology that is transitional between Middle and Upper Paleolithic implement types, the Streletsian – contained more beads than have been found in the entire Pleistocene sites of the rest of the world (Bednarik, 1995). They yielded 13,113 small ivory beads and over 250 perforated canine teeth of the polar fox. By this time, perhaps 28,000 years ago, the art of bead making had reached an extraordinary level, in which the results of thousands of hours of labor were lavished on just three burials. In India, we have only a few specimens from the entire Paleolithic:

two from Bhimbetka, south of Bhopal, and three from Patne, Maharashtra (Fig. 7). Two of the latter are not perforated, although one is centrally scored (Bednarik, 1997). Other Asian regions producing ostrich eggshell beads include Siberia (Krasnyi Yar, Trans-Baykal), Inner Mongolia (Hutouliang), and the Gobi desert in northern China and Mongolia. The ostrich, now extinct in Asia, was widely distributed to the end of the Pleistocene, occurring in the Arabian Peninsula until well into historical times.

Both southern and northern Africa have yielded countless finds of worked ostrich eggshell (Baur-Röger, 1987, 1988; Camps-Fabrer, 1962, 1966, 1975; Czesla, 1986; Goodwin, 1929; Marmier & Trecolle, 1979; Marshall,

1976; Sandelowsky, 1971; Woodhouse, 1997). In the far north of Africa, the Caspian, belonging already to the first half of the Holocene, yielded not only numerous figurative and nonfigurative engravings on ostrich eggshell fragments, but also beads of snail shells, teeth, and small stones,

besides those of ostrich eggshell. The southern African sites providing such finds date from the Middle Stone Age right up to recent periods. Ostrich eggshell beads from Bushman Shelter near Ohrigstad, Transvaal, have been suggested to date from somewhere between 12,000 and 47,000 years ago. Beads of this material span a vast age spectrum, still occurring in recent periods in southern Africa. For instance, they are found in the Smithfield B, a tool complex of the subcontinent's interior regions of the fourteenth to seventeenth centuries AD. Indeed, ostrich eggshell beads are among the most enduring symbolic artifacts in human history. Much the same can be said about other forms of beads. For instance, a publication about Palestinian jewelry of the most recent ethnographic past features a photograph of a bead described as a "fossilized sea urchin" (Helmecke, 1990: Pl. 13f), depicting in fact a crinoid fossil cast that closely resembles the crinoids recovered from the Acheulian site Gesher Benot Ya'aqov in the same region, on the River Jordan (Goren-Inbar et al., 1991). Although separated by hundreds of millennia in time, the same materials were used for the same class of symbolic artifacts over an enormous time span – a poignant

reminder that in terms of their humanness, our distant ancestors were a great deal closer to us than many archaeologists are willing to concede.

Beer Production in Peru

Lidio M. Valdez

MacEwan University, Edmonton, AB, Canada

Fermented beverages, produced from a variety of raw materials, constitute one of the most widely consumed drinks around the world. Indeed, there is tantalizing evidence that indicates that all past civilizations produced and consumed alcohol. Such a pattern continues in contemporary times as these beverages are produced and consumed within almost every culture around the world. Ancient western South America was no exception. First, early accounts left by the Spaniards, such as those of Cieza de León (1962 [1552]), Sarmiento de Gamboa (1999 [1572]), and Father Cobo (1956 [1653]), provide valuable information in regard to the use of fermented beverages within the Inka Empire. These sources note that these drinks were so important to the Inka state that it was directly involved in its production and distribution. Second, archaeological research confirms to a large extent the reports left by the Spaniards and demonstrates that at the time of the Inkas, alcohol was widely used across the Andes (Hastorf, 1991; Morris, 1979). More importantly, archaeological research demonstrates that these drinks were already produced and consumed in the region long before the rise of the Inka Empire (Moore 1989; Shimada, 1994; Gero, 1990; Valdez, 1994, 2006). Finally, ethnographic evidence shows that alcohol continues to be produced and consumed across the Andes (Camino, 1987; Hayashida, 2008, 2009; Jennings, 2005; Valdez, 2012).

As initially observed by the Spaniards for the particular case of the Inka, these beverages are produced from almost any vegetable or fruit but in particular, from maize (*Zea mays*) (Fig. 1), the berries of the molle tree (*Schinus molle* L.) (Fig. 2), the fruit of the algarrobo tree (*Prosopis* sp.) (Fig. 3), quinoa grains (*Chenopodium quinoa*), peanuts (*Arachis hypogaea*), and manioc (*Manihot esculenta*). Native Quechua speakers distinguish each drink type by a name, such as

Beer Production in Peru, Fig. 1 Maize used for maize beer

qora aqa for the one made from maize, *molle aqa* for the one made from molle tree berries, and *masato* (Izaguirre, 1924, p. 72) for the one made from manioc tubers. Currently, all these beverage types are commonly called *chicha*, a name that Spaniards such as Sarmiento de Gamboa (1999 [1572]) and Betanzos (1924 [1551]) had learned elsewhere before their arrival to the Central Andean region and began identifying every type of fermented beverage under this single label. It can be stated, nevertheless, that *chicha* is a name more commonly associated with maize beer (*qora aqa*) than with the other beverages.

In contemporary times, the most commonly produced and consumed beverage type in most of Peru, particularly in the highlands and the western lowlands, is maize beer. This wider acceptance of maize beer appears to be connected with the wider availability of maize in the region. In the central highland region, consumption of maize beer is closely followed by molle beer. Molle trees and therefore molle berries are locally available, especially at elevations below 3,000 m asl. Alcohol produced from quinoa seeds occurs also in the highland region, although more often among the people who inhabit higher elevations, often above 3,000 m asl. Along the western lowlands, alcohol made from the fruits of the algarrobo tree also occurs, along with maize beer. Algarrobo trees are found mainly along the Pacific coast. Finally, on the eastern slopes of the Andes, the most

Beer Production in Peru, Fig. 2 Molle berries (a, immediately after harvest; b, once stepping; c, ready for soaking; d, after soaking)

common types are drinks made from manioc tubers and peanut seeds. Along with the above beverage types, all made from indigenous raw materials, there is one additional alcohol type produced from a nonnative crop, sugar cane (*Saccharum*). In the central highlands and the eastern lowlands, this beverage is called *warapo*.

All these fermented beverages are prepared differently and some are more time-consuming than others. On the one extreme, the one that is

most labor intensive is maize beer. Maize grains must be selected, soaked, malted (Fig. 4), dried, crushed (Fig. 5), boiled, and finally drained in order to ferment. This process is long and it can take a minimum of 18–21 days. As its production is costly and as maize is a highly valued crop because it is also food and can be exchanged for other crops, maize beer is a highly prized drink. Therefore, this is the beverage type that one would expect to find at celebrations such as

Beer Production in Peru, Fig. 3 Algarrobo fruits

Beer Production in Peru, Fig. 4 Malted maize grains

weddings and Andean rituals. On the other extreme, the beverage type that is least labor intensive is molle beer. Indeed, once the molle berries are harvested, the beverage can be ready for consumption in just 3 days. The production involves only soaking the berries in special open-mouth vessels, draining the sweetened liquid, and placing it in narrow-neck ceramic jars for fermentation (Valdez, 2012). Molle beer can be produced on short notice and with the involvement of just two individuals. Since it can be produced quickly and with little effort, molle beer is often consumed at celebrations that involve large gatherings, such as carnival.

Depending on the crop being used, the preparation of these drinks varies. Those produced from maize, manioc, quinoa, and peanuts require boiling, while those made from molle berries and

algarrobo fruits involve only soaking. These differences also imply that their production often requires different equipment. For instance, maize beer and peanut beer production involves the use of grinding stones. In contrast, such tools are not necessary in the production of molle beer or manioc beer. In addition, the production of drinks in general involves the use of various ceramic vessel types. If the production involves boiling, medium-size open-mouth vessels are needed. If the production of a beer type involves soaking, large-sized open-mouth vessels (Fig. 6) are required. Finally, for the purposes of fermentation, large-sized narrow-neck vessels (Fig. 7) are required; an exception is manioc beer because it ferments in hollowed logs. The fermentation process, in almost all the cases, takes only between 2 and 3 days. Unfermented beverage is sweet (Fig. 8); the presence of foam (Fig. 9) emerging at the mouth of the container indicates that the beverage has fermented and is ready for consumption. Storage life is limited; once fermented, the drink becomes undrinkable within just 3 days.

Each beverage type is unique, with a particular flavor, some of which are stronger than others. Such is the difference that each of them leaves a strong aroma in the fermenting vessels. Consequently, vessels used for fermenting one type of beverage (e.g., molle beer) cannot be used for fermenting another beverage type. Therefore, it is common, at least in the central highlands region, that households have several narrow-neck fermenting vessels. The lack of vessels for the purposes of fermenting a particular type of beverage can be solved by borrowing one from a kin.

It is equally important to stress that the vessel types used in the process of producing these drinks, including manioc beer and *warapo*, are the same. These consist of:

1. Medium-sized, open-mouth, round-body vessels called *ollas* or *mankas* (for boiling)
2. Large-sized, open-mouth, round-body vessels called *maqma* (for soaking)
3. Large-sized, narrow-neck, round-body vessels called *urpu* (for fermenting)

Beer Production in Peru,
Fig. 5 Crashing malted
 maize for boiling

Beer Production in Peru, Fig. 6 Open-mouth ceramic
 vessel ideal for soaking molle berries

4. Medium-sized, narrow-neck, round-body vessels called *qipiri* (for transporting)
5. A variety of small-sized cups (for drinking)

As noted elsewhere (Valdez, 2012), the type of vessel used in the production of maize beer and molle beer overlaps and the same can be stated for the other drink types, again the exception

Beer Production in Peru, Fig. 7 Narrow-neck large
 vessel ideal for fermentation

being *masato*. All the other beverages ferment in narrow-neck vessels.

Continuing with the long tradition that predates the Inka Empire, these alcohol types are still produced in most of current Peru, in most cases likely following the same steps as in ancient

Beer Production in Peru, Fig. 8 Unfermented molle beer (upi)

Beer Production in Peru, Fig. 9 Fermented molle beer

times. In regions such as the central highlands, for example, one reason for this continuity is that alcohol plays an important role in the reciprocal obligations that the people of the region maintain. Indeed, communal labor, or any activity that

Beer Production in Peru, Fig. 10 A glass of molle beer ready to drink

brings together a large number of working parties, involves the distribution and consumption of alcohol, in addition to food and coca leaves. The hosting household has the obligation to provide goods that include alcohol. Providing water – instead of alcohol – could be a serious mistake because in the immediate future, it will become nearly impossible to recruit the desired number of working personnel. In a region where inhabitants are closely linked and their activities are carried out collectively, being marginalized could easily make life very challenging.

Finally, fermented beverages are also produced for the market. Indeed, there are households specialized in their production which make them available on a weekly basis. Such households are called *chicherías* (in Spanish) or *aqa wasis* (in Quechua). The most common drink types produced for the market are maize and molle beer (Fig. 10). In urban areas, written signs placed at the entrance of the houses indicate the availability of the fermented beverages. In rural areas, the signs consist of a piece of cloth tied at the end of a stick and placed by the door (like a flag) and indicate maize beer or a bunch of molle leaves tied at the end of a stick and placed by the entrance of the house signals the availability of molle beer.

Ben Cao Gang Mu

Liao Yuqun

The application of herbal, mineral, animal, and man-made substances in medical therapy has been recorded in China since antiquity. These pharmaceutical compilations are called *Ben Cao*.

In the Ming dynasty, a masterpiece, *Ben Cao Gang Mu* (Compendium of Materia Medica), was published in AD 1590. In China, as well as in other parts of the world, this work is the best known and most respected description of traditional pharmaceuticals. The value of this enormous achievement, written by one person, goes far beyond the scope of a pharmaceutical-medical drug work. In fact, it constitutes an extensive encyclopedia of knowledge concerning nature and the technology required for the medicinal use of nature.

The compilation of *Ben Cao Gang Mu* was based on the *Zheng Lei Ben Cao* (Classified Materia Medica, compiled at the end of the eleventh century AD). ► [Li Shizhen](#), the author, took from it 1,479 drugs. He supplemented these with 39 drugs that had been included in the drug compendia of the Jin Yuan period, as well as with 374 drugs that he himself described for the first time, so that the *Ben Cao Gang Mu* contained a total of 1,892 drugs. This number is confirmed by the table of contents; the actual number should be 1,898. To continue the statistics: the number of drug illustrations is 1,160 and that of the recorded prescriptions is 1,196, of which Li Shizhen collected or newly compiled 161 himself.

The entire work was divided into 2 chapters of illustrations and another 52 chapters containing the

texts. The first four text chapters are of a general nature; chapters 5 through 52 contain the monographs. The total number of drugs was divided into 16 groups, and then 60 subgroups. Thus, for example, the group of herbs was divided into the subgroups of mountain herbs, aromatic herbs, swamp herbs, poisonous herbs, convolvulose herbs, water herbs, stone herbs, moss and lichen herbs, and finally, various herbs.

For each drug the following ten items were discussed. As they were used only when the information was necessary, not all are contained in each monograph:

1. Information concerning a previously false classification of the drug
2. Information on secondary names of the drug, including the sources of these names
3. Collected explanations
4. The pharmaceutical-technological preparation of the drug
5. Explanation of doubtful points
6. Correction of mistakes
7. Information on the thermo-influence and taste of the drug
8. Enumeration of the main indications of the drug
9. Explanations concerning the effects of the drug
10. Enumeration of prescriptions in which the drug is used

As for the author, Li Shizhen was born into a medical practitioner's family. When he was unable to pass the official career exams after three attempts, he was determined to devote himself to the study of medicine. Through 30 years' clinical practice and learning from many experts, he, after innumerable hardships, completed the manuscript in 1578, but the first edition was not finished until after his death.

²Department of Pharmacology, Varadmn Mahavir Medical College, Safdarjang, New Delhi, India

³Rice Research Station, CCS Haryana Agricultural University, Kaithal, Haryana, India

Betel leaf and betel/areca nut are important plants in the Asiatic region and are individually masticatory but are generally taken together as *betel quid* or *paan* with other ingredients as catechu, slaked lime, spices, sweeteners, essences, and tobacco. Betel quid chewing is often culturally or socially ritualized, and there are elaborate ceremonies attending its use in various Asian and Pacific cultures though those are stigmatized in the West. The importance of *paan* can be best judged from the English rendering of a Sanskrit sloka [verse], "A mouth devoid of Vedas, the juice of *tambula* and witty sayings, is said to be a mere hole" (Krishnamurthy, 2009; Gode, 1961). The Thais prefer to go without rice or food rather than to deprive themselves of betel (Rooney, 1993).

The areca nut palm (*Areca catechu* L. family Palmaceae) is an unbranching, long plant extending up to 15 m and crowned with 6–9 fronds. The areca nut, botanically a drupe, is the seed found within the egg-sized fruit. The nut may be used fresh or dried and cured before use,

by sun drying, baking, roasting, boiling, and fermenting which change the flavor of the nut and its astringency. The genus *Areca* has two species in India: *A. catechu* L. and *A. nagensis* Griff. of the Naga Hills. There are many cultivated varieties such as *jahaju* (long nut), *manak chandi* (sphere), and so on. In the Pacific islands, betel nut palms are grouped into two cultivars: red and white. It needs a tropical wet climate with evenly distributed rainfall of 1,500–5,000 mm.

The betel vine (*Piper betle* L. family, Piperaceae) is a perennial creeper cultivated for its heart-shaped leaf. It needs fertile soils with proper shade and irrigation and is grown in hotter and damper parts of India. The Rural and Agricultural Glossary offers a number of terms related to betel cultivation and rituals performed during cultivation. Cultivation and plucking is ceremoniously done (Crooke, 1888, 1896; Gupta, 1991; Roy & Vijayalaxmi, 2013). Records on varieties are found in Hular inscription (1077 AD) of Vikramaditya IV and Krishni Gita in Malayalam. The latter provides information on 15 vines and seven nut varieties, their features and uses.

Both plants are cultivated mainly in India, Malaysia, Polynesia, Micronesia, and South Pacific Islands. The origin is likely to be in Southeast Asia where they grow naturally and diversity is greatest with archeological evidences dating back to 10,000 BC (Gorman, 1970). In addition, there is extraordinary diversity of indigenous words for duo in these regions. The Sanskrit word *tambula* for *paan* owes its origin to the Malaysian region and is derived from the term *tembel*.

There is no mention of *tambula* (betel leaf) in the Vedic *Samhitā*, the *Brāhmanas* and *Sūtras*, the *Rāmāyaṇa*, the *Māhābhārata*, and the *Smritis* of Manu. *Tambula* was probably introduced to India from the South Sea Islands such as Java, Sumatra, during the early Gupta period (Gode, 1961). The Mon Khmer-speaking Khasis, one of the earliest tribes to migrate to Assam, are reputed to have brought it in Assam and are the originators of betel chewing (Das, 1992).

Though there was a lot of opposition from religious people, it slowly entered into the social

and religious life of the people as food, medicine, and an item of rituals, and the commodity became a daily necessity. Both became the favorite pastime of elite society and royal persons and were used for royal gifts exchanged between emperors. *Paan* was used in welcoming guests, as a token of honor, pledge, and love. Betel nut chewing is cited as one of the eight enjoyments of royal life in the eleventh-century text called *Manasollasa* or Splendour of Thought. Such travelers as Marco Polo and Ibn Baṭṭūṭa of the thirteenth and fourteenth century mentioned it. As betel nut chewing evolved, so have the accessories used to make *quids* which include fine boxes and seed cutters.

Betel leaf vine and areca nut became important crops in Assam Bengal Hosur, Gadang, Dharwar, Kolhapur and Vijayanagar, South Kanara, Bellary, and Arcot during the eighth and tenth centuries. They also became an important commodity of trade and commerce and earned revenue for the royal treasury (Neog, 1960; Gode, 1961; Swamy, 1973).

The Assamese social, cultural, and religious life is webbed around the two and offers a view of its possible uses in various walks of life. For an Assamese a dream house is one with a courtyard with areca nut trees and betel leaf creepers. Betel chewing is a luxury indulged in by everyone. Khasi etiquette requires exchange of *kwai* as a mark of good breeding, and heaven is a place where one gets betel to one's heart's content. The reception at a social gathering starts with it and ends with it. In the past distance was measured by *khasi*, the number of *kwai* (areca nuts) chewed on the way. Every laborer expects *kwai* in addition to their wages. Khasis place a tamol over a dead body and say, "Farewell, go to the God and chew a tamol with Him." The Ahoms of Assam include tamol in the items offered to the Goddess *Sulichani* and to the almighty. Bodos also do the same in their *Kheral* puja before clearing land (Das, 1992).

Chewing *paan* is not common to the Santhals of Bengal, but they use the two along with many herbs in mouth sores, chest pain, redness and blood in urine, venereal disease (Chancre), hemoptysis, and bronchitis. Roots of *Piper betle*

are used to shut the womb (to stop pregnancy). The stem of *Piper betle* is used in curing madness (Bodding, 2001).

In India, a betel leaf is considered sacred and used to sprinkle holy water at religious ceremonies and offered to Lord Shiva, Lord Vishnu, and other Gods. The betel nut itself is worshipped symbolically as an image of Ganesha. It is customary in Maharashtra to use two betel leaves at all *paan-supari* ceremonies on the occasions of marriage, social functions, and religious festivals (Ahuja & Ahuja, 2011). In Bihar and Awad, the marriage pavilion is prepared with green bamboo and betel leaves, and bundles of seven betels are sent to the boy's father through a barber (Croke, 1888).

The betel is in itself a symbolic language. As rolled betel leaf symbolizes affection, the exchange of *tambula* denotes friendship and restores lost friendship (Ahuja & Ahuja, 2011). Sending a messenger anywhere and offering him a preparation of areca nut is tantamount to saying, "you have my authority" or "you carry my confidence" (Neog, 1960). Used as a simile, betel leaf conveys beauty, shyness, slimness, delicateness, and parts of the body such as lips, while the betel nut conveys the color of the lover. Metaphorically betel quid refers to vanity and worthlessness of place. Symbolically its presentation means affection and love, while socially and in the royal court, it denotes time for departure or time to call off a meeting. The duo has penetrated many Indian languages. Many villages and towns in Assam derive their name from betel, betel nut, or quid: Tamol bari, Pan bari, Chunpura, Chunpora, Tamulinga, and Gauhati. Penang, an island on the northwest coast of Malaysia, derives its name from *Pulau Penang* which means island of the areca nut palm. Houses in Jakarta, Indonesia, are called *Pondok Pinang* (areca nut hut) and *Kehon Sireh* (betel garden). Ko Mak in Thailand and Fua Mulaku in Maldives are also named after the areca nut. Betel is so pervasive that it is part of religion and has penetrated into the vocabularies of Hindi, Gujarati, Assamese, Tamil, Telugu, and other Indian languages. No other post-meal item has attained such an important position except rice.

A number of phrases in these languages are derived from words associated with these two plants. In addition, a number of sayings, proverbs, riddles, folk tales, and songs come from the duo (Ahuja & Ahuja, 2011). It is no wonder that a culture of sayings on suitable time and area of cultivation, planting, spacing, water requirements, time of maturity, and quality of betel leaf and nut also exists (Ahuja & Ahuja, 2012).

In addition to uses in social, personal, and religious ceremonies, the duo is seen in a number of medicinal and ethnobotanical uses (Table 1).

According to the universal classification of food, the areca nut and the betel leaf complement each other and are, therefore, in harmony. Since the areca nut is "hot" and the betel leaf is "cool," they act together to keep the human body in balance. In Āyurveda, betel leaves and betel nuts are both used as medicine in various forms like the leaf juice, the leaf itself, and the betel quid as adjuvant along with other Ayurvedic preparations. Āyurveda regards the nut as heavy for digestion and cooling, as it is dry and astringent in taste. It destroys *pitta* (bile) and *kapha* (phlegm), is intoxicating, and is both a stimulant and a laxative. The raw and unripe nut is poisonous and harmful to the eyesight. The cured hard center is excellent for destroying all three *doshas*. All organisms are sustained by three humors: *pitta* (bile), *kapha* (phlegm), and *vayu* (wind) called *dhatu*s in their equilibrium state. When this equilibrium is disturbed, disease occurs, and in this state they are called *doshas*. Disease occurs either by the aggravation or attenuation of *doshas* (Sadhale & Dave, 2006; Ahuja, Ahuja, Sharma et al., 2007).

In general it can be said that the betel nut is like poison when young, purgative in the middle stage, but an elixir when fully ripe and dry. The nut should therefore be taken only in the third stage. Burnt betel nuts are esteemed as tooth powder. A paste of betel nuts is used as laxative, and mixed with sandalwood it is useful in intrinsic hemorrhage (Sharma, 1996). Areca nut is also used in various cosmetic and aromatic preparations. It was also used to induce flowering in the *Champa* tree. An ointment made with areca nut in

Betel Nuts, Table 1 Ethnobotanical uses of betel nut and betel leaves

State	Tribe	Use
Assam	Miris	Nut and leaves used as vegetable
Bengal	Kols	Leaf used in wound by trident along with other constituents
Meghalaya	Khasi and Jaintia	Leaf juice for optic problems
Bengal	Santhals	Ground leaf with <i>Citrus medica</i> , roots of <i>Randia uliginosa</i> as a drink for colic conditions
		<i>Acacia catechu</i> , <i>Achyranthes aspera</i> , and <i>Randia uliginosa</i> in a betel quid taken for strangulation of the intestine
		Roots of <i>Piper betel</i> used to shut the womb (prevent pregnancy)
		Leaves with nut for hemoptysis and bronchitis
		Betel leaf + 15 other plants for biliary colic
		Betel leaf + roots of <i>Gymnema hirsutum</i> and <i>Nigella indica</i> for venereal disease
Meghalaya	Khasi and Jaintia	Betel leaf juice as indelible ink
	Khasi	Exchange of betel nut is etiquette
		Number of betel nuts chewed on the way is used to measure distance
		Welcoming guest and chance meeting with reciprocal offer of betel nut
		Reception of a social function starts with betel nut
		Exchange of kwai betel nut is correct and accepted way of leave taking at the end of function
Assam		Breaking ice between unknown and welcoming a known person
	Khasi	Betel nut considered as cheap and efficacious mean of hospitality
		Offer in betel nut after a meal in Assam
		First item offered to a visitor at home
Bhutan		Doma zhes “please have betel leaves and areca nut” each time two individuals meet, at the end of a meal and all occasions
		Betel leaf and small piece of areca nut offered to guest at ceremonies, BL and BN in a plate during archery games, official ceremonies, BL and BN passed round after a dinner

sesame oil along with other items is used to cure the swelling of shoulders in cattle (Ayangarya, 2006).

Betel leaves are useful in diseases caused by deranged phlegm (*kapha*) and in control of filarial infection, obesity, and skin diseases (Sharma, 1996). It is also used to relieve cerebral congestion and satyriasis and to allay thirst. *Paan* leaves are used as ready dressing for foul ulcers and with honey are used for coughs. Public singers and criers commonly chew the root to improve their voices. Betel quid chewing promotes health in damp areas (Watt, 1889). Ground leaves of *betel*, along with other plants, are used to cure bloat in cattle and as an antihelminthic for dogs.

According to *Yunani* physicians, betel nut is considered a diuretic; it strengthens the heart and

regulates menstrual flow. It is used for overcoming swollen eyes, mental confusion, chronic urinary distress, and pus formation. It is also a nerve tonic and an aphrodisiac.

Paan chewing with betel nut is popularly believed to prevent tooth decay, but long-term use has been associated with oral submucous fibrosis (OSF), precancerous oral lesions (mouth wounds), and squamous cell carcinoma (cancer). Acute effects of betel chewing include worsening of asthma, low blood pressure, and rapid heart-beat. Harmful effects of areca are roughness in the chest and urinary stones anemia and the appearance of jaundice (Krishnamurthy, 2009). The epidemic proportion of oral cancer in India is due to betel nut chewing (Chaturvedi, 2010). The risk of developing carcinoma of the oral mucosa is 7.7 times higher in betel chewers than in others.

Pharmacology or Drug Action

Betel chewing has been claimed to produce a sense of well-being, euphoria, heightened alertness, sweating, salivation, a hot sensation in the body, and increased capacity to work, but it also leads to habituation, addiction, and withdrawal. However, the mechanisms underlying these effects remain poorly understood. The areca nut kernel contains catechu, tannin, gallic acid, oily matter, gum, and characteristic alkaloids. The main active component, the alkaloid arecoline, has potent cholinergic [neurological] activity and is readily absorbed into the body. Pharmacologically the action of arecoline is a violent stimulant of the parasympathetic nervous system. Arecoline also stimulates salivation and decreases sweating, sweetens the breath, strengthens the gums, and generates a mild exhilaration giving the feeling of a good disposition. In the presence of lime, arecoline and guvacoline in areca nut are hydrolyzed into arecaidine and guvacine, respectively, which are strong inhibitors of GABA uptake. Arecoline hydrobromide is a statutory drug in the Indian, British, German, and French pharmacopoeias. Taenine is a preparation containing areca nut extract, forming a liquid medicine used in veterinary practices against tapeworms (Krishnamurthy, 2009).

The specific burning taste of betel leaf is derived from the presence of volatile oil consisting of phenols (chavibetol, chavicol) and terpenes which stimulate the release of catecholamines in vitro. It exhibits carminative, stimulant, astringent, and aromatic properties. The leaf extract, fractions, and purified compounds play a role in oral hygiene, antidiabetic, cardiovascular, anti-inflammatory/immunomodulatory, antiulcer, hepato-protective and anti-infective, etc. Patents were also awarded for some of its biological activities such as anti-inflammatory, anticancer, and immunomodulatory actions associated with leaf extracts and purified compounds. A number of biologically active compounds have potential for use as medicines, nutraceuticals, and industrial compounds (Kumar et al., 2010).

Betel chewing also increases plasma concentrations of norepinephrine and epinephrine.

These results suggest that betel chewing mainly affects the central and autonomic nervous systems (Chu, 2001). Let the *paan* live the same glorious life as it has in the past. We now know we have to show restraint in eating and avoiding its excessive use.

Bezoar Stones in Peru

Marcia C. Stephenson

Purdue University, West Lafayette, IN, USA

Precious stones and gems have played a major role in Eastern and Western histories of medicine. One particular kind of stone, the bezoar stone, was especially valued in European medicine in the sixteenth and seventeenth centuries. Bezoar stones are compacted masses or concretions generally formed in the stomach or intestinal tract of animals. They come in a range of sizes, shapes, consistencies, and colors, some reaching the size of a chicken egg. Although the stones are formed in animals everywhere, only those bezoars originating in specific kinds of ruminants from Asia and Peru were believed to have healing virtue.

Europeans learned about bezoars primarily from the writings of two physicians from the Iberian Peninsula. One was the Portuguese physician of Spanish and Jewish origin, Garcia da Orta (ca. 1501–1568), who discussed Asian bezoar stones in his book *Colóquios dos simples e drogas e cousas medicinais da India* (Colloquies on the simples and drugs of India) published in Goa in 1563. Nicolás Monardes (ca. 1493–1588), a noted physician from Seville, included a treatise on the Asian bezoar stone with his first publication in 1565 on New World materia medica, *Dos libros. El uno trata de todas las cosas que traen nuestras Indias occidentales, que sirven al uso de medicina, y como se ha de usar de la rayz del Mechoacan, purga excelentissima. El otro libro, trata de dos medicinas maravillosas que son contra todo veneno, la piedra bezaar, y la yerva escuerçonera. Con la cura de los venenados*. (Two books. One is all things that we have brought from the West Indies which serve the use of medicine. . . . The other book describes two wonderful medicines that are useful against every poison, the bezoar stone, and the yerva escuerçonera.) Monardes later expanded his original presentation of bezoars when he received the first non-Asian stones that were sent to him from Peru by a Spanish soldier. He described these new stones in a second publication on New World medicines, *Segunda parte del libro de las cosas que se traen de nuestras Indias Occidentales, que sirven al uso de medicina* (Second part of the book of the things that have been brought from the West Indies which serve the use of medicine) (1571). He documented their medicinal use and effectiveness in his third and final book on American materia medica: *Primera y segvnda y tercera partes de la Historia medicinal de las cosas que se traen de nuestras Indias Occidentales que siruen en medicina* (Joyfull newes out of the Newe Founde Worlde) (1574). This publication included the first two books as well as new material.

When preparing his treatise on the Asian bezoar stone, Monardes (1565) drew upon his own experience as well as on the writings of famous scholars such as Moses Maimonides

(ca. 1138–1204) and other Persian, Arab, and Jewish philosopher-physicians writing in the ninth through the twelfth centuries who described the physical characteristics of the stones, the kind of animal in which they were found, and the ways that they could be used in medicine. The early sources that Monardes consulted provided two explanations for how the stones were formed inside the animal. According to one description, a rare deer-goat (*cervicabra*) found in the mountains of Asia would seek out and devour poisonous snakes at certain times of the year and then, as the poison heated its body, submerge itself in a cool lake or river. The hot sun would draw the poison from its body, concentrating it in tears that formed and hardened in the corners of the animal's eyes. When the animal came back to the water's edge, the tears would drop off on the shores where they would later be found and collected. According to the second account, after eating the poisonous serpents and taking to the water to cool off its body, the animal would then consume healing plants. These plants and herbs would concentrate the poison in the gut where it subsequently formed a hard ball or stone comprised of layers of poison and healing virtue (Monardes, 1574, pp. 134r–136r).

Considered to be powerful antidotes to many kinds of poisons, bezoars were also thought to be effective remedies for a number of devastating illnesses such as deadly fevers, fainting, melancholy, epilepsy, heart palpitations, vertigo, colic, worms, and poisoned wounds. Treatment called for the stones to be crushed and the resulting powder to be applied directly to a lesion or mixed in a beverage to neutralize any poison that might have been slipped in. In addition to being utilized as a medicinal simple, the stones could be mixed with other ingredients to make a composite medicine such as the costly Gascon's Powder which included bezoar, red coral, black crab claws, and white amber, among other items. Bezoars circulated mainly among European royalty, the nobility, and Church elites, and they were safeguarded in royal pharmacies and in the fashionable cabinets of curiosities in vogue at the time.

Bezoars were treasured and expensive because they were difficult to obtain and the risk that one

had purchased a counterfeit stone was high. Monardes included numerous case examples from his sources that dramatized the stone's healing virtue and priceless value. One such account, from the writings of the Spanish-Moorish physician Abdallah Narach, told of the events that took place when al-Nāṣir, or, as he was referred to by Christians, Miramamolín (amir al-muminin) (O'Callaghan, 1983, p. 244), emir of Cordoba, was saved after having been poisoned because someone gave him a bezoar stone. Miramamolín was so thankful to have had his life spared that he allegedly offered the Royal Alcazar of Cordoba to the man who came to his aid (Monardes, 1574, pp. 138v–139r).

Following its publication in 1565, the first part of Monardes's writings on New World medicines served as a useful manual for people in the New World as well as in Europe. Soldiers in Peru who had read the treatise on the bezoar noticed what looked like an Andean variety of the Asian goat-deer that Monardes had described. After hunting and killing several of these exotic beasts, the soldiers opened them up, and guided by a young boy who was among the Indians accompanying them, they found the precious stones inside the animals' gut. The news of this exciting discovery was published in the second part of the *Historia medicinal* (1571). One of the soldiers involved in the hunt, Pedro de Osma, sent Monardes samples of the stones so that he could experiment with them and write about his findings. Coming across this new source of bezoars was a monumental event for the Spanish because it meant that they could compete with Portugal's lucrative monopoly of Asian stones. It wasn't long before a substantial trade of Peruvian bezoars began circulating throughout the New World and Europe. The Jesuits figured prominently among the protagonists involved in the trade, actively dispatching large quantities of bezoars from the San Pablo Jesuit School in Lima to Rome (Martín, 2001, p. 125).

Although Monardes never named the exotic Peruvian creature found to have bezoars, some of his contemporaries later identified it as the vicuña (*Vicugna vicugna*), one of the two species of undomesticated Andean camelids, along with the guanaco (*Lama guanicoe*). Bezoars found in

vicuñas and guanacos were believed to have the greatest medicinal virtue, although those harvested from the domesticated alpaca (*Vicugna pacos*) and llama (*Lama glama*) were also prized. When word spread that these valuable stones could be found in the two species of wild camelids, soldiers and others began hunting them in great numbers. Consequently, from an ecological standpoint, the discovery of the stones in these animals was a decisive factor in the devastating decline in the vicuña and guanaco populations.

The Spanish learned that bezoar stones also played an important role in Andean indigenous herding communities. Known as *illa* in Quechua and *hayntilla* and *illa* in Aymara, bezoar stones were kept by pastoral families in sacred bundles called *señalu q'epi* along with other ceremonial objects. Anthropologist Denise Arnold studied midwife singers from the herding community of Qaqachaka, Bolivia, and described how the women ritually care for the stones by washing and rewrapping them at the same time that they remember the histories of these *illas* through commemorative songs. By means of these rituals, the stones are symbolically transformed into seeds of renewal that help to ensure the health and reproduction of the family's herd and thus guarantee the future livelihood of the family and the community.

When Spanish inquisitors, or "visitors of idolatries" as they were known in the New World, found these stones in homes and storehouses, they feared that they formed part of the dangerous forces of Satan in the Andes and so they seized and burned as many as possible. Of course, given the stone's value in European medicine, it is likely that many were smuggled out and sold for a handsome profit. For indigenous herding communities, the seizure of the stones from their homes and sacred bundles and the assault on their traditional rituals of commemoration meant that their lives had been turned upside down. The loss of the stones or regenerating seeds signified that their power of regeneration and continuity had been placed at risk. Consequently, the disappearance of the stones represented the beginning of a new era, the primary characteristic of which was hunger due to the threat that the communities' animals might similarly vanish.

By the end of the eighteenth century, medical interest in Asian and Peruvian bezoar stones had largely faded, and today they are of interest primarily for their historical resonance. For Andean indigenous pastoral communities, in contrast, bezoars still hold relevance today as a vital symbol of the regeneration and persistence of Andean knowledge and traditions.

Bhāskara I

Agathe Tamar Keller

Bhāskara I was a seventh century astronomer, probably from the region that is between the border of modern day Mahārashtra, Gujarat, and Madhya Pradesh in India.

He wrote two treatises in the line of ► **Āryabhaṭa I's** astronomy, the *Mahābhāskariya* (Shukla, 1960) and the *Laghubhāskariya* (Shukla, 1963). Bhāskara did not just restate in an explicit way Āryabhaṭa I's astronomy; he also provided explanations and interpretations of this astronomer's reasoning. Bhāskara I is also the author of a commentary on the *Āryabhaṭīya* (see the entry on Āryabhaṭa). This is the oldest known Sanskrit commentary on this treatise. It is also the oldest known commentary for the whole mathematical and astronomical tradition in Sanskrit. The commentary is called the *Āryabhaṭīyabhāṣya* (Keller, 2006; Shukla, 1976). Bhāskara I himself dates the writing of this text to 628 AD. He is thus a contemporary of ► **Brahmagupta**.

This commentary, not being written in compact *sūtra* verses, can help us reconstruct what astronomy and mathematics were for a seventh century astronomer. It gives us precious insights into how mathematical and astronomical concepts were derived and discussed. Bhāskara, for instance, discusses the relation of mathematics to astronomy, giving several definitions of mathematics in the opening part of his commentary. His idea of *gaṇita* (computation, mathematics) seems to be quite malleable and open. Indeed, if the discipline called *gaṇita* is understood as a set of procedures, general (*samānya*) or specified (*viśeṣa*), then it encompasses astronomy (*jyotiṣa*). But it can also be seen as a set of specialized subjects. In this case, it is quite separate from astronomy. Bhāskara provides us with different proposals as to how one can classify the subjects related to mathematics. He thus states for the first time the classification of

mathematics into eight *vyavahāras*, which were used after him in arithmetical texts (see the entry on arithmetic in India). He also alludes to equations (*bija*) as a way of classifying mathematical subjects, an idea that had a certain posterity in the algebraic tradition in India (see the entry on algebra in India). For Bhāskara I all computations belonged both to arithmetic (*rāśigaṇita*) and to geometry (*kṣetragaṇita*). Thus series (*średdhi*) are seen as both sums of numbers (belonging thus to arithmetic) and piles of objects (belonging thus to geometry).

Bhāskara's commentary also testifies to how astronomy and mathematics were practiced in those times. For instance, Bhāskara gives details on the constructions of gnomons (sundials), describing various shapes, styles and schools for this instrument. He also sometimes explains how a mathematician (*gaṇaka*) uses a working surface (probably just the bare ground or a slate) on which numbers are disposed and diagrams drawn. These were then used when solving problems, which involve moving quantities, or seeing a proof in a drawn figure (Keller, 2005).

Bhāskara's commentary on the *Āryabhaṭīya* is an important landmark in understanding the beginning of sine trigonometry. His work shows us that the fundamental diagram of sine trigonometry is a bow field (*dhanuḥkṣetra*). A bow field is composed of a back (*prsthā*), a chord (*vyā*) and an arrow (*śara*). This is illustrated in Fig. 1.

By the time Bhāskara wrote his commentary, it was fairly common to consider something that can be a bit confusing at first, the half-chord of the half-arc. That is, in Fig. 2, the segment AO is the half-chord of $a/2$, and not the half-chord of a . This segment is what we call the sine of arc $a/2$, when in a circle of radius 1. In Bhāskara's mathematics, however, circles are seldom with a unit radius, and so he deals in fact with R sines, e.g., R times the sine. This segment is called *ardhajyā* (lit. half-chord), but slowly as it became a technical term in itself, the word half (*ardha*) was sometimes dropped, until the segment itself was called *jyā*. The innovation constituted by the sine over the chord becomes clear if we look at Fig. 2

Bhāskara I, Fig. 1 A bow field (Drawing by the author)

Bhāskara I, Fig. 2 The half-chord of the half-arc (Drawing by the author)

again. Indeed, by using this segment, computations using the Pythagorean theorem become possible enabling one to derive lengths of segments quite easily. To explain how to derive tables of sine differences, Bhāskara prescribed the construction of a diagram, which is shown in Fig. 3 (Hayashi & Yano, 1991). It can be seen as an ancestor of our trigonometric circle.

As a mathematician, Bhāskara did not restrict himself to trigonometry but provided his insights on a great range of subjects. For instance he gave a detailed version of different problems solved by

Bhāskara I,**Fig. 3** Bhāskara's diagram for deriving sines

B

a pulverizer (e.g., a method to solve Pell equations, Bag, 1979), all sorts of variations on the Pythagorean theorem, reflections on the concept of quadratic irrationals (Chemla & Keller, 2002; Datta 1980), and many others (Rao, 2006). As a scholar, he often staged intellectual debates and took positions on them, thus letting us have a feel for the oppositions existing between different schools of mathematicians and authors that existed at the time, something that Brahmagupta's work also testifies to.

Bhāskara's legacy has been especially felt in Kerala. If you judge the popularity of an author as being measured by the number of commentaries it has given rise to, we can note that in Kerala, his works were commented upon by Govindasvāmin (ca. 825), Śaṅkaranārāyaṇa (ca. 869) and Parameśvara (ca. 1430). After first being confused with his namesake ► **Bhāskara II** by early nineteenth century scholars (Datta, 1930), his work was slowly brought to light in the early twentieth century (Datta & Singh, 1938). Finally K. S. Shukla took the time to edit his texts and translate his treatises in the 1960s and 1970s.

Bhāskara II

R. C. Gupta

Undoubtedly, the greatest name in the history of ancient and medieval Indian astronomy and mathematics is that of Bhāskarācārya (b. AD 1114). His *Līlāvātī* is the most popular book of traditional Indian mathematics. He is usually designated as Bhāskara II in order to differentiate him from his earlier namesake who flourished in the early part of the seventh century.

According to Bhāskara's own statement towards the end of his *Golādhyāya*, he was born in Śaka AD 1036 or AD 1114. He also adds that he came from Vijjāḍaviḍa near the Sahya mountain. This place is usually identified with the modern Bijapur in Mysore. S.B. Dikshit is of the opinion that Bhāskara's original home was Pāṭaṇa (in Khandesh), where a relevant inscription was discovered by Bhau Daji in 1865. According to the inscription, Manoratha, Maheśvara, Lakṣmīdhara, and Caṇgadeva were the names of the grandfather, father, son, and grandson, respectively, of Bhāskara. Caṇgadeva was the chief astronomer in the court of the king Siṅghaṇa and had established in AD 1207 a *maṭha* (residential institution) for the study of the works of his grandfather. Bhāskara's father, Maheśvara, was also his teacher.

Bhāskara's *Līlāvātī* (The Beautiful) is a standard work of Hindu mathematics. It belongs to the class of works called *pāṭī* or *pāṭīgaṇita*; that is, elementary mathematics covering arithmetic, algebra, geometry, and mensuration. Its popularity is shown by the fact that it is still used as a textbook in the Sanskrit medium institutions throughout India. It provides the basic mathematics necessary for the study of almost all practical problems, including astronomy. The subject matter is presented through rules and examples in the form of about 270 verses which can be easily remembered. There is a story that the author

named the work to console his daughter Līlāvātī, who could not be married due to some unfortunate circumstances; but the truth of the story cannot be ascertained. Bhāskara addressed the problems to a charming female Līlāvātī, who, according to some scholars was his wife (and not his daughter).

The great popularity of *Līlāvātī* is illustrated by the large number of commentaries written on it since it was composed about AD 1150. Some of the Sanskrit commentators were: Parameśvara (about 1430), Gaṇeśa (1545), Munīśvara (about 1635), and Rāmakṛṣṇa (1687). Only a few of these have been published. Gaḍeśa's gives a good exposition of the text with a demonstration of the rules. However, the best traditional commentary is the *Kriyākramakarī* (ca. 1534), which is a joint work of Śaṅkara Vāriyar and Mahiṣamaṅgala Nārāyaṇa (who completed it after the demise of Śaṅkara).

There are a number of commentaries and versions in regional Indian languages. Quite a few modern scholars have edited, commented on, and translated *Līlāvātī*. At least three Persian translations are known, the earliest being by Abū al-Fayḍ Fayḍī (AD 1587). The English translation by Colebrooke (1817) was based on the original Sanskrit text and commentaries.

Bhāskara's *Bījagaṇita* (Algebra) is a standard treatise on Hindu algebra. It served as a textbook for Sanskrit medium courses in higher mathematics. In it the author included an exposition of the subject based on earlier works. Among the sources named were the algebraic works of ► Śrīdhara and Padmanābha. Besides operations with various types of numbers (positive, negative, zero, and surds), it deals with algebraic, simultaneous, and indeterminate equations. There is a separate chapter on the Indian cyclic method called *cakravāla*. He attributes the method to earlier teachers but does not specify any name. Due to the difficult nature of some of the topics, the *Bījagaṇita* was not as popular as the *Līlāvātī*.

Bhāskara's *Siddhānta-śiromaṇi* (AD 1150) is an equally standard textbook on Hindu

astronomy. It has two sections: *Grahaṇita* (Planetary Mathematics) and the *Golādhyāya* (Spherics). Often these two sections appear as independent works. There is a lucid commentary on the whole work by the author himself. It is called *Mitākṣarā* or *Vāsanābhāṣya*. Other commentators include Lakṣmīdāsa, Nṛsiṃha, Munīśvara (1638/1645), and Rāmakṛṣṇa. The 14th chapter of the *Golādhyāya* is the *Jyotpatti*, which may be regarded as a small tract on Hindu trigonometry.

Usually it is customary to regard *Līlāvātī*, *Bījagaṇita*, *Grahaṇita*, and the *Golādhyāya* as the four parts of the *Siddhānta Śiromaṇi* which make it a comprehensive treatise of Bhāskarācārya's Hindu mathematical sciences. His two other works are the *Karaṇa-kutūhala* (whose epoch is 1183), a handbook of astronomy, and a commentary on Lalla's *Śiṣyadhīvr̥ddhidatāntara* (eighth century AD). Some other works have also been attributed to him, but his authorship of *Bījopānaya* is questionable.

Bhāskara introduced a simple concept of arithmetical infinity through what he calls a *khahara*, which is defined by a positive quantity divided by zero, e.g., $3/0$. His arithmetical and algebraic works are full of recreational problems to provide interesting pedagogical examples.

Perhaps the most important part of Bhāskara's *Algebra* is his exposition of the Indian cyclic method. We now know that the method was already known to Jayadeva (eleventh century AD or earlier). A modern expert, the late Selenius, praised it by remarking that "no European performance in the whole field of algebra at a time much later than Bhāskara II, nay nearly up to our times, equaled the marvelous complexity and ingenuity of cakravāla method." Fermat proposed the equation $61x^2 + 1 = y^2$ in 1657 to Frénicle as a challenge problem. However, by applying the above method, Bhāskara had already solved the problem five centuries earlier. Bhāskara's solution (which he got just in a few lines) in its smallest integers was $x = 226,153,980$, $y = 1,766,319,049$.

The feat was possible not only due to the technique but also because of a well-developed symbolic notation. Colebrook remarks.

Had an earlier translation of Hindu mathematical treatises been made and given to the public, especially to the early mathematicians in Europe, the progress of mathematics would have been much more rapid, since algebraic symbolism would have reached its perfection long before the days of Descartes, Pascal, and Newton.

Another gem from Bhāskara's *Algebra* is a very short proof of the so-called Pythagorean theorem.

The geometrical portion of *Līlāvātī* covers mensuration regarding triangles, quadrilaterals, circles, and spheres. A special rule gives the numerical lengths of the sides of regular polygons (from three to nine sides) in a circle of radius 60,000. The last chapter entitled *Aṅka-pāśa* is devoted to combinatorics.

Bhāskara's *Jyotpatti* contains many trigonometrical novelties which appear in India first in this tract.

Although an equivalent of the differential calculus formula

$$\Delta \sin \theta = \cos \theta \Delta \theta$$

already appeared in Munījla's *Laghumānasa* (AD 932), Bhāskara II gave its geometrical demonstration. He knew that when a variable attains an extremum, its differential vanishes. A crude method of infinitesimal integration is implied in his derivation of the formula for the surface of a sphere. This he gave in the *Vāsanābhāṣya* on the *Golādhyāya* (Chap. III).

Bhāskara's *Siddhānta-śiromaṇi* is one of the most celebrated works of Hindu astronomy. It is a comprehensive work of *Brahma-pakṣa*. He praised ► [Brahmagupta](#), who belonged to the same school, but his own astronomical work became more famous.

Although based on the works of predecessors, rather than on any fresh astronomical observations, the *Siddhānta-śiromaṇi* served as an excellent textbook. Systematic presentation of the

subject matter, lucidity of style, and simple rationales of the formulas made it quite popular. It also contained some improved methods and new examples. For instance, he gave a very ingenious method of finding the altitude of the Sun in any desired direction in his *Golādhyāya* (III, 46). His professional expertise and all-round knowledge made him a truly great and revered *ācārya* (professor) of Hindu astronomy and mathematics for generations.

Bian Que

Liao Yuqun

Bian Que, one of the most famous medical men in ancient China, lived during the time of the Zhou dynasty, between 500 and 600 BCE. He was good at various subjects in medicine and skilled in diagnosis and treatment, especially in pulse-taking and acupuncture.

Sima Qian (about 145–196 BCE), a well-known historian, wrote a biography of Bian Que in his work *Shi Ji* (Historical Record). In it, he discussed Bian Que's practicing medicine, wandering from town to town and effecting miraculous cures, even bringing the dying back to life. In the end Bian Que was killed by a jealous commissioner of the Imperial Academy of Medicine. Sima Qian says: "Bian Que expounded medicine as the guiding principle of (medical) technique; the later generations followed it and could not change any more." He was regarded as the founder of traditional Chinese medicine, but according to the historical materials in the biography, Bian Que lived and flourished for hundreds of years. That is because its author confused him with another famous medical man, Qin Yueren. Probably Qin Yueren was a follower of Bian Que's teachings.

In the earliest bibliography, *Qi Lue*, written in the first century BCE, Bian Que was assumed to be the author of some medical works such as *Bian Que Nei Jing* (The Internal Classic of Bian Que) and *Bian Que Wai Jing* (The External Classic of Bian Que). Although all of them have been lost, the contents can be partly found in other extant

medical works, which reflect what he contributed to traditional Chinese medicine.

Bian Que said that the blood and *qi* (vital energy) move along the channels of the body, making 50 circuits per day. Some medical historians consider this the first intimation of the circulatory system of the blood; others are more skeptical. This view was constructed on the principle of cyclicism, a very common mode of thought for the Chinese.

It was he, too, who founded the extremely complicated old Chinese system of pulse-taking, according to which a doctor was supposed to be able to diagnose an illness solely by the condition of the pulse. It was not just a question of whether the beat was strong or weak, regular or uneven. Pulses could also be distinguished as “sounding like a sickle, first exuberant then dying away”; “flowing along quietly like flying hair or feathers”; “beating deep and strong like a thrown stone”; “sounding delicate like the string of an instrument”; or “slipping along like a fish or a piece of wood on the waves”. From the above selection of possible pulse beats, it is easy to see with what extraordinarily sharpened sensitivity the Chinese doctor examined his patient. Bian Que also discussed how to diagnose illness by the condition of the complexion. For example, a yellow complexion and nails were an indication of jaundice; red dealt with the heart; and white was always due to the lungs.

As for therapy, Bian Que used the traditional techniques such as acupuncture, ► [moxibustion](#), and drugs to cure various diseases. We do not know who invented those treatments; however, all of them were improved owing to Bian Que’s practice and teaching. Indeed, these are still followed in clinical practice and diagnosis today.

Bitumen in China

Hans Ulrich Vogel

Reports of bitumen seepages and production concentrate on four provinces: northern Shaanxi and eastern Gansu from the Han period onward, Sichuan from the Ming onward, and Xinjiang which has records of bitumen seepages during the periods of the Northern Dynasties (386–581), the Tang, and the Qing. In addition, during the Ming and Qing periods, minor production sites existed in Guangdong, Taiwan, Zhejiang, Anhui, and Liaoning (Liaodung).

The earliest record of bitumen seepages refers to northern Shaanxi that is the oil fields of Yanchang and Yongping of today. The *Hanshu*, first century AD, states that in Gaonu district (modern-day Yan’an) “there is the Wei River; it can burn.” This statement is elucidated by later sources, which say that on the water of the Wei River “fat” (*fei*) is floating which can burn and which can be taken for greasing cart axles or as fuel for lamps.

Sources from the Song onward provide more details on the locations of Shaanxi petroleum seepages and production methods. In his famous account of about 1070 on using petroleum carbon for ink, Shen Gua (1031–1095) mentions the production of “stone oil” (*shiyou*) in the two prefectures Fu and Yan and of “stone juice” (*shiye*) in Yanchuan. He wrote that stone oil grew in the sand and stones of the waterfront, was mixed with spring water, and, with a view to ink manufacture, was produced inexhaustibly within the earth, in contrast to the limited supply of pine wood. In spring, local people collected it with pheasant tail brushes and put it into pots. The method of collection described by Shen Gua is similar to that described in Agricola’s *De re metallica* of the mid-sixteenth century.

Song and Yuan sources report that near Yan’an bitumen was used to make so-called “stone candles” (*shizhu*). Lu You (1125–1210) says in his *Laouxuean biji* of 1190 that they are

solid like stone and give a very bright light. Moreover, “they also gutter like wax [candles]. Their smoke, however, is thick and may fumigate and defile curtains and clothes. This is why people in the western [part of the empire] do not esteem them.” The stone cave supplying the raw material for the production of the stone candles was, however, closed in 1270 by government order.

Perhaps the first notion of a well intentionally dug for getting bitumen can be found in the *Da Yuan da yitongzhi*, the comprehensive administrative and geographical description of the Yuan period:

South of Yanchang district, at Yinghe, there is a stone oil well which has been cut open. Its oil can burn and also cures itches and ringworms of the six domestic animals. Annually, 110 *jin* [pounds] are handed in. Moreover, in Yongping village, 80 *li* north-west of Yanchuan district, there is another well, which annually procures 400 *jin*. They are handed over to the [Shaanxi] Route (*lu*).

As in many other cases, the output of oil seepages was low. The record also shows that the government was heavily interested in this resource, probably because of its importance for warfare.

The use of bitumen in warfare from the Yumen oil field in western Gansu is reported by an eighth-century source, stating that, in 578, the Emperor Wu of the Northern Zhou, when being besieged by the Turks at Jinquan, took this “fat” and set it afire, thus burning the enemies’ assault weapons. When brought into contact with water, it burnt even more, with the result that Jinquan was saved.

With the development of deep drilling, Sichuan became an important producer of bitumen, being a by-product of the search for brine and, later, natural gas. Sixteenth-century accounts report that the sources of the fire wells of Jiading and Qianwei are all “oily.” Because of its odor, locals call the stone oil “realgar oil” (*xionghuangyou*) and “sulfur oil” (*liuhuangyou*). It was thought that the sources and veins of stone fat, realgar, and sulfur were interconnected. Officials filled ► [bamboo](#) tubes with oil and ignited it for lighting the way. Moreover, special iron

lamps were constructed which fitted the use of bitumen as fuel. An indigenous terminology developed which was based on the colors of bitumen. White bitumen was called “rice-soup oil” (*mitangyou*), green “green-bean oil” (*ludouyou*), yellow “gardenia-nut oil” (*zhiziyou*), and black “black-lacquer oil” (*moqiyou*). Petroleum occurred at depths of 180–220 m, ca. 360 m, and 950–990 m, and there were experts who knew exactly to which depths the hoisting buckets should be sent to have them filled with petroleum exclusively.

The most important application of bitumen in crude and distilled form was certainly in the military field, where it was used for incendiary weapons. The sources do not inform us about details of the processing and distilling methods, but this may be due to the fact that these were treated as military secrets. The second most important use of bitumen was for lighting purposes, for which numerous references, particularly for regions near bitumen seepages or wells, can be found. In Sichuan, bitumen appears to have served sometimes as fuel for the evaporation of brine. Bituminous products were also used for greasing cart axles and the bearings of water power trip-hammers, manufacturing ink, sealing leather wine sacks, covering floors, and tempering iron.

Moreover, bitumen was often applied for medical, pharmaceutical, and alchemical purposes. For instance, Li Shizhen’s *Bencao gangmu*, published in 1596, states that it is smeared on ulcers, ringworms, worms, and scabies, and is used for drugs which heal flesh wounds caused by iron arrows. A source of the seventh century tells us that when swallowing the bitumen of Jiuzi in Xinjiang, fallen out teeth and hair can be induced to grow again. Later sources are less sanguine about internal application and sometimes stress that bitumen is poisonous.

Although, in China, bitumen seepages and deposits were discovered and used from an early period onward, the overall economic, technical, and scientific role of bitumen remained small and did not extend much beyond the limits of the small number of production areas. The only exemption was in the military field, where

testimonies of fire and flame throwers using distilled petroleum are numerous. The revolutionary impact of the Drake Well in mid-nineteenth century Pennsylvania was not due to the depth reached in deep drilling, but to the fact that beforehand a thorough scientific investigation of the properties, refining methods, and possible applications of petroleum had taken place. It was this combination of scientific investigation, technical achievement, establishment of production plants, and creation of a huge demand that was responsible for the rise of the petroleum industry in the West.

Games in Ancient Egypt and the Near East

Most ancient board games are race games, where the players move pieces from an origin to a goal. The player who finishes the track first wins the game. The rules of the game can vary; they may be agreed upon between both players before a game begins. From their earliest origins, games illustrate the metaphor of armed conflicts. Therefore, fighting and hunting scenes are often present in works of art related to games.

A great variety of dice have been used to determine the movement of the pieces. Among the most ancient types are knucklebones, typically the astragalus bone of a sheep or goat, whose four unique faces meant they could be thrown to give different results. Casting sticks functioned as the principal randomizing agent in Egypt since the Predynastic period, and tetrahedral dice were popular in Mesopotamia from an early date. The origin of cubic dice remains somewhat mysterious and is probably to be found in the Indus Valley.

Game boards have been found in elaborate and humble versions, in materials ranging from gold-inlaid ivory to wood and clay, suggesting that members of all socioeconomic classes play games. Despite their popularity, the original names and rules of some ancient games remain unknown.

The human fascination for games has probably been linked to a desire to control chance since a very early date. Board games often went beyond the playful dimension, to be used for divination. The players' fate depended on the result of dice, reflecting the will of the gods. Funerary archaeology demonstrates that games occupied a specific place in the rite of passage into the hereafter.

The small size of the boards allowed one to travel with them easily. From the second millennium BCE, Egypt and the Near East shared a number of different games. The four most commonly found games in those regions, sometimes closely associated on bifacial boards, will be described here.

Mehen

The oldest known board game is the game of *mehen*, which has been found in Egyptian tombs dating to the Predynastic (3500–3000 BCE) period. Multiple boards from this time period show that it was a board in the shape of a coiled snake, with a segmented body designating the playing area. Sometimes, the form of the serpent is abstracted, particularly in the Second-Dynasty (2890–2686 BCE) examples from the necropolis at Abydos (Amélineau, 1905). The number of spaces represented on the boards varies, and no diagnostic markings have been found on any of the boards designating particular spaces on the boards. Likewise, the first known artistic representation of a board, from the Third-Dynasty (2686–2613 BCE) tomb of Hesy-Re, does not show spaces that appear to be marked in any way (Quibell, 1913). The number of spaces in the game board is not fixed and can vary greatly.

The name *mehen* first appears in an inscription in the Fourth-Dynasty (2613–2498 BCE) tomb of Prince Rahotep (Petrie, 1892). The game shares its name with the Egyptian serpent god Mehen, which, according to different cosmologies, was either an obstacle to be overcome during the soul's journey through the underworld or the protector of the sun god Ra during his daily journey through the underworld. In either case, there was a connection between this game, the serpent god, and the underworld. In the Pyramid Texts, a series of inscriptions on the walls of the Pyramids of Old Kingdom pharaohs, one of the utterances suggests a belief that attainment of the afterlife was achievable by successfully transiting the mehen game board (Piccione, 1990b).

Further connection between the game and ritual activity can be seen on tomb reliefs dating

to the Fifth (2498–2345 BCE) and Sixth Dynasties (2345–2181 BCE). In these depictions, players are shown in contexts of feasting, music, and dancing as part of the celebrations of the goddess Hathor that accompanied the funeral of the deceased. In particular, the mastaba (a type of tomb) of Idu shows the son of the deceased playing mehen against an opponent, with others playing senet around them (Simpson, 1976).

The popularity of mehen in Egypt seems to have waned during the later years of the Old Kingdom, and no boards are known after the end of the second millennium BCE. No known boards have been found dating after the Second Dynasty, though their existence can be inferred from textual references in the Fourth Dynasty and the aforementioned tomb reliefs from the Fifth and Sixth Dynasties. One tomb relief is known from the Twenty-Sixth Dynasty (672–525 BCE) that appears to depict mehen, but it is believed that this relief is a copy of an Old Kingdom original, as were other artifacts dating to that Dynasty (Piccione, 1990b).

There is some evidence that mehen may have been played outside of Egypt. In the Levant and Cyprus, flat stones with depressions arranged in a spiral pattern have been found which could reflect the spread of the game outside of its homeland (Fig. 1). Such stones have been found at Lachish and at Bab edh-Dra (Rast & Schaub, 2003; Tufnell, 1958). The most compelling evidence identifying this type of stone as games has been found in Cyprus, where the game appears on the opposite side of stones displaying three rows of ten depressions (Swiny, 1986), which probably reflects the Egyptian game of senet (see below). In contrast to Egypt, mehen appears to have enjoyed greater longevity, as mehen boards have been found dating to the latter part of the second millennium BCE. In contrast to Egypt, where all the evidence for the play of mehen is related to mortuary ritual, archaeology in Cyprus has shown that mehen was played in domestic contexts at sites such as Sotira *Kaminoudhia* and Marki *Alonia*. Evidence also suggests that mehen was played in communal areas, perhaps at feasting events, on the island.

Board Games in Antiquity, Fig. 1 Mehen game from Episkopi *Phaneromeni* in Cyprus. Late Cypriot I (1700–1450 BCE)

Many senet boards dating to the New Kingdom (1549–1077 BCE) have another game on the opposite side, known as the game of 20 squares. This game has its origins in Mesopotamia and is nearly as old as senet and mehen, though it only appeared in Egypt during the New Kingdom.

Senet

Senet, perhaps the best-known game of the ancient world, has similar origins to mehen in Predynastic Egypt and was indeed one of the longest-lived games in human history, as it is known from archaeological contexts spanning roughly 3,000 years (Fig. 2). Early examples of the game are rare and fragmentary, but it existed in its canonical form (three rows of ten spaces) by the Third Dynasty, where it appears alongside mehen in the tomb painting of Hesy-Re. The appellation “*znt*,” transliterated as senet, first appears in the tomb of Prince Rahotep and is translated as “passing,” most likely due to its strong connotation with the passing of the soul through the underworld to the afterlife, a connection which is more explicit in later periods (Kendall, 1978; Piccione, 1990b).

While senet also appears in the tomb reliefs of the Fifth and Sixth Dynasties, no complete boards are known until the Middle Kingdom (2061–1690 BCE), at which point it appears to have been the most popular game in Egypt. Its popularity increased during the New Kingdom, when it became an essential mortuary accoutrement and was included in the Book of the Dead. It was believed to be a tool in communicating with the dead, and numerous tomb reliefs from the Old Kingdom already show deceased people playing against the living. Its mortuary connotations existed in the Old Kingdom, as it was included in scenes of rituals dedicated to the goddess Hathor: the same scenes are discussed above in relation to that game (Piccione, 2007). Many texts throughout Egyptian history attest to the ability of the game to facilitate the movement of the deceased’s spirit both through the netherworld and back to the world of the living, acting as a connection between life and death (Piccione, 1990a, 2007). During the Late Period (672–332 BCE), the senet board became conceptualized as the netherworld itself, and moving pieces through the spaces actualized the passage of the player/deceased through it (Piccione, 2007, p. 60). By the New Kingdom, it was common to depict the deceased playing senet alone. It is similar to the divination seen in other games, in which the living were attempting to communicate with and influence the supernatural.

In addition to the canonical three rows of ten playing spaces, senet also has distinctive patterns of markings in some of the squares that aid in identification of archaeological examples of this game, typically limited to the final five spaces of the board. These spaces, marked with hieroglyphs indicating danger or good fortune, likely affected the play of senet (Fig. 3).

Much like mehen, senet is also known outside of Egypt from an early date. It can be attested at Early Bronze Age 2 (3000–2700 BCE) Arad in the southern Levant, where 43 boards are known (Sebbanë, 2001). All of them are flat pieces of limestone, but the manner in which the senet pattern is displayed varies: it can either be delineated with etched squares, rows of depressions, or a combination of the two methods. These games

appear at the site during a period of intense interaction with Egypt but disappear after the Egyptians turn their attentions elsewhere.

In Cyprus, many more senet games are known (Swiny, 1980, 1986). In fact, there are more known senet games from Cyprus (330) than from Egypt (120). Its appearance on the island is later than that of mehen and probably corresponds to more intense involvement of Egypt at the major port of Byblos, on the coast of modern

Lebanon. Once the game spread through the island, it became part of everyday life, much as mehen did, with examples found in domestic and in communal settings which may indicate feasting. Senet does seem to have been played in everyday settings in Egypt as well, as it can be found etched into limestone ostraca (a piece of stone broken off from a vase) at the Valley of the Kings, presumably cast aside by workers or artisans building the tombs there, and in pavements of ancient temples throughout Egypt.

The Game of 20 Squares

The game of 20 squares – from the number of playing squares it contains – was certainly one of the most popular games in the ancient Near East. It is also known as the Royal Game of Ur, since its most famous and earliest examples were discovered in elite tombs from the Sumerian city of Ur, in southern Iraq (Woolley, 1934, pp. 274–279, pls. 95–98). Two kinds of dice (four-sided stick dice and tetrahedrons with two marked corners) were associated with the boards at Ur, as well as seven counters for each player. The early version of the 20-square game has also been found in a funerary context, at Shahr-i Sokhta, in

Board Games in

Antiquity, Fig. 4 Senet game inscribed for Amenhotep III, reportedly from Thebes, Egypt, Dynasty 18, ca. 1390–1353 BCE. Brooklyn Museum, Charles Edwin Wilbour Fund, 49.56a-b. Creative Commons-BY

Southeastern Iran (Piperno & Salvatori, 1983). The playing squares are outlined by the coils of a snake, carved in relief on a wooden board forming a block of 4×3 squares joined by a “bridge” of two squares to a smaller block of 2×3 . Both date from the mid-third millennium BCE and attest to the cultural contacts between individuals involved in long-distance trade.

At the turn of the third to the second millennium BCE, the game of 20 squares underwent a slight change in the layout of the board: while the block of 4×3 squares was maintained, the central row now contained 12 squares without a block of 2×3 (Fig. 4). This new variant was first seen in the Kerman region in Iran (Dunn-Vaturi & Schädler, 2006, pp. 2–3, Fig. 1; Madjidzadeh, 2003, pp. 120, 197). There, illicit excavations in ancient cemeteries around Jiroft have brought to light several specimens of zoomorphic gaming boards made of chlorite (Dunn-Vaturi & Schädler, 2006, pp. 4–6, pls. 1, 2a, 3; Madjidzadeh, 2003, pp. 130–136 and 200–201). The boards appear to have never been used for playing, suggesting that they were probably intentionally produced as grave goods. This assumption is corroborated by the choice of the animals: birds of prey, snake, and scorpion. Apart from the fact that these threatening and agile creatures correspond to the competitiveness required in a race game, it seems that an apotropaic (having the power to avert evil influences) and chthonic (relating to the underworld) aspect

characterizes these animals, which also transcend the human sphere, serving as a link between the earth and the underworld (snake, scorpion) and the heavens (bird), respectively.

The same period witnessed the spread of the game westward and was found in a playing context in the form of graffiti on the courtyard pavement of the Amorite palace at Mari in Syria (Parrot, 1958, pp. 13, 46–47, 182, 247, 258). The second millennium BCE was a time of increased intercultural interaction in the Eastern Mediterranean, promoted through the exchange and use of elite artifacts like game boxes manufactured of expensive materials such as ivory and decorated in the International Style. The game of 20 squares was introduced to Egypt during the seventeenth century BCE and is attested there from the Seventeenth to the mid-Twentieth Dynasties. Most of the time, the playing grid is on the upper face of a game box with the Egyptian senet game on the opposite side. While many of these games were found in graves, one example from the artisans’ village at Deir el-Medina demonstrates that it was played by Egyptians and not restricted to a funerary item. The game of 20 squares has a longer history in the Near East than in Egypt. It was in vogue until the mid-first millennium BCE in Syria–Palestine and Mesopotamia, the region to which it was native. More than 100 examples in total are known to date (de Voogt, Dunn-Vaturi, & Eerkens, 2013, p. 1718, Fig. 1, Table 1).

Board Games in Antiquity, Fig. 5 Game box for playing senet and 20 squares, Thebes, el-Asasif, Egypt, Dynasty 17-early Dynasty 18, ca. 1635–1458 BC-E. Metropolitan Museum of Art, New York. Rogers Fund, 1916, 16.10.475a

It is generally assumed that the four squares on each side of the board served as entry squares for the counters. Consequently, the counters of each player met only in the central row where they could be captured and returned to their starting points. The aim of the game seems to have been to move one's counters down that central line to the final square and off the board (Fig. 5). Specially marked squares, found on a number of boards, allow the player certain privileges, like safety from being captured or another throw. These special marks, a cross, a rosette, or an inscription, are placed four squares distant from each other. A late-Babylonian cuneiform tablet dating to 177–176 BCE provides significant detail on how the game proceeds (Finkel, 2007). The game is called “a pack of dogs,” whereas the counters (five on each side) bear the names of birds. They are moved according to the throw of two knucklebones, and special results are needed to enter each of the bird counters into the game. The obverse of the tablet is inscribed with a zodiacal divinatory diagram, and one would be tempted to interpret the five birds of the game and its central row of 12 squares in an astrological context. The foretelling aspect of the game of 20 squares is corroborated by liver-shaped boards from the Levant, which refer to hepatoscopy, divination by the liver of an animal or bird (Becker, 2007; Finkel, 2007, pp. 25–26; Meyer, 1982, pp. 65–69).

Board Games in Antiquity, Fig. 6 Game of Hounds and Jackals, Thebes, el-Asasif, Egypt, Middle Kingdom, Dynasty 12, reign of Amenemhat IV, ca. 1814–1805 BC-E. Metropolitan Museum of Art, New York. Purchase, Edward S. Harkness Gift, 1926, 26.7.1287a-k

The Game of 58 Holes

The modern name of this game refers to two symmetrical circuits of 29 perforations, each one to be completed by a player, thus making a total of 58 holes on the board. Howard Carter named the same game “Hounds contra Jackals” (Carnarvon & Carter, 1912) after a unique ivory set excavated in Thebes in 1910 (Fig. 6). Since its discovery, this particular board has become iconic due not only to its delicate nature but also because it is the only example retaining its pegs: five carved in the form of a hound's head and five with a jackal's head. The most likely route of play starts at the holes next to the palm tree fronds and continues down the center of the board, around the outer edge, and up to the thirtieth and finish hole. The progress of the race was affected by links between the holes and hieroglyphs marking special holes. The links could be shortcuts or penalties, like in the modern game “Snakes and Ladders,” with a playing piece sent forward or backward. From hole 10 onward, every fifth hole is emphasized. It is assumed that the hieroglyph nefer (“good” or “beautiful”), marked on two positions, was beneficial to players that landed on them, similar to square 26 on senet boards. The goal is a larger hole surrounded by the

hieroglyph shen that may have meant “end of the track.” The player who first reached this sign, also interpreted as “eternity,” was possibly believed to have achieved success in his quest for immortality.

Playing accessories, as well as objects imitating games such as pendants, are linked to the deceased’s journey to the afterlife and thus often found among burial goods. The jackal deity Anubis was responsible for the mummification and protection of the dead through the netherworld. His connection to funerary devices in the form of jackal-headed playing pieces is therefore relevant (DuQuesnes, 2002, pp. 157–158, no. 72). Moreover, the choice of animals known for their quickness as playing pieces is appropriate for a race game. Anubis pegs could perform the necessary ritual on the board which would symbolize the deceased’s body. Connections between boards and human representations are made through shapes or anatomical details, such as the eyes, and support the idea of rebirth. Sophie Erdős suggests that the holes on the body-shaped board had to be passed through by the pegs to allow the deceased to be born again (Erdős, 1986, pp. 118–119).

Carl Schuster includes the game of Hounds and Jackals in his “rebirth gaming board” category. Schuster makes the comparison between the paths to complete on our game and the Indian game called “Ladder of Deliverance” (an earlier form of “Snakes and Ladders”), whose compartments symbolize various reincarnations. Furthermore, Schuster compares the shield-shaped boards of 58 holes to a drawing made by the Malekulans of Vanuatu: “The Malekulan artist first punched a framework of dots in the sand, then drew an unbroken, never-ending line around these dots to form a figure identified as, simultaneously, Human Ancestor and Cosmic Turtle. . . . In many ancient and tribal societies, the human body served as a genealogical chart. Joint-marks represented the souls of primary ancestors. To achieve reunion with one’s ancestry (and thereby qualify for rebirth), a continuous line connecting each joint might be drawn to form an image of the First One. Or a sequence could be followed on a gaming board, with peg holes equivalent to the

guide dots of sand drawings. The immediate goal was to ‘re-member the First One’” (Schuster & Carpenter, 1996, pp. 280, 288).

The archaeological evidence for the game points to its origin in Egypt at the turn of the second millennium BCE. In contrast to senet, played for more than 3,000 years, the game of Hounds and Jackals is almost exclusively attested during the Middle Kingdom (2030–1640 BCE) within Egypt. The increasing importance of senet in funerary rituals during the New Kingdom may explain this phenomenon. Military campaigns and trade relations facilitated the game’s spread from Nubia to Central Anatolia very quickly after its invention. The game was popular throughout the Near East, including the Iranian plateau, until the mid-first millennium BCE. There are about 70 known examples of this game (de Voogt et al., 2013, pp. 1718–1719, Fig. 3, Table 2). Other methods were introduced on the playing surface to provide linkage and indicate special holes (size, color, motif). Rosettes on Near Eastern boards are the equivalent of the nefer hieroglyph which brought promotion to the player. During the Iron Age at the turn of the second to the first millennium BCE, Iranian boards (now in the British Museum and the Musée du Louvre) show contrasting links between the holes that cross from side to side. This element changed the nature of the game, which became more complex and increased interaction between the players.

Games in Asia, the Americas, and Africa

Other board games are known in India and China but are less well documented than those from the Eastern Mediterranean. Some of these games differ from those discussed above, as they are not all race games. There is suspicion that the game of 20 squares may have originated in India, based on fragmentary boards found at Lothal (Rao, 1985) and Mohenjo-Daro (Mackay, 1938), dating to the third millennium BCE. Not enough is known about the context of these boards to be able to determine what their roles in divination were, but later references to games in Hindu literature

suggest relationships between games, astronomy, and cosmology in early Hindu belief (Soar, 2007). In China, the game known as liubo is attested from tombs dating to the fourth century BCE (Mackenzie, 2004), but little is known about its role in society.

The game of patolli was known in ancient Mesoamerica from the days of Teotihuacan (possibly as early as 200 BCE) until the time of the Spanish Conquest, when the Spanish chroniclers documented it. Much less is known about this game than those of the Old World antiquity, as there is little reference to it in the extant writings of peoples of Mesoamerica, but it has been found at many sites throughout the region and awaits further study.

Patolli appears in a number of the Aztec codices collected by the Spanish and usually depicts two players around a board but with little other information about the game. The boards depicted in the codices show an "X"-shaped game, with each arc of the X containing two rows of squares which vary in number. These boards differ from the arrangement of spaces in the games which have been found by archaeologists, but nevertheless, it seems most likely that these patterns were indeed some kind of game (Swezey & Bittman, 1983). Most of the examples found consist of a circuit of squares, arranged in a square pattern, with two rows of squares crossing in the middle. There are variations to this pattern, but the variations seem to be merely elaborated versions of the basic pattern, rather than a completely different game (Gallegos Gomora, 1994).

Aside from those depicted in the codices, the patolli boards that have been found have exclusively been engraved into stone pavements or architectural features, commonly among the patio groups and temples known throughout the pre-Columbian Mesoamerica. While these games await further study to determine patterns in when and where they were played, some indications suggest that they were played by those who were observing solar or astronomical events or those who were taking part in other rituals, as evidenced by their appearance on top of the Temple of the Hieroglyphic Stairway at Naranjo in Guatemala (Morales & Fialko, 2010).

In Africa, mancala games are well documented from ethnographic and historic sources, but little is known about the games on the continent from archaeological contexts. This is likely due to the fact that most mancala games are either made of wood or holes scooped out of the dirt (de Voogt, 1997) and thus not preserved archaeologically. In some places, artificial depressions are found in rock outcroppings that could be games, but they are difficult to identify as such and almost impossible to date. These difficulties are also apparent in other regions, where patterns of squares or depressions have been found. The best ways to determine whether a pattern of squares or depressions are a game is if they are arranged in a pattern unique to a certain game (such as 20 squares or 58 holes), if they are accompanied by another known game (such as mehen and senet on Cyprus), or if they can be connected chronologically to a known modern or historical game (such as liubo in China or patolli in Mesoamerica). There were likely more games in the ancient world than are currently known, but knowledge of them is hindered by preservation and identification issues.

Boats in Goa

Zeeshan Alli Shaikh

Archaeology, Faculty of Humanities, University of Southampton, Centre for Maritime Archaeology, Southampton, UK

Goa is a small state on the west coast of India with an area of 3,701 km². Its geographic position is marked by 15048'00"N and 14053'54"N Latitude and 74020'13"E and 73040'33"E Longitude. Major rivers, such as Zuari and Mandovi, and minor rivers, such as Sal, Tiracol, and Chapora, flow in Goa. Goa shares its boundary with Maharashtra state in the north, in the South with the northern part of Karnataka, in the east with the Sahyadri mountain range, and in the west with the Arabian Sea. Sandy beaches separated by rocky headlands, cliffs, and broad estuaries have fashioned the coastline of Goa. Such a geography and geomorphology have contributed greatly to the development of a boatbuilding

Boats in Goa, Fig. 1 Boat motifs portrayed on ancient memorial stones found in Goa (Photo: A. S. Gaur, 2007)

industry and distribution of different types of traditional boats.

Traditional folk songs of Goa often mention *Vodem* which means boat. There are boat motifs portrayed on ancient memorial stones (Fig. 1) which suggests that the people of Goa were aware of the art of boatbuilding from ancient times (Gaur & Kerkar, 2007; Kamat, 2008). The people of Goa who have continued their profession of fishing and preserved their traditional knowledge about boatbuilding till today are locally known as “Kharvi” (Fig. 2).

Traditional Boatbuilding

Before we understand how traditional boats in Goa are built, it is important to know the different raw materials required to build boats and the various stages involved in the boatbuilding tradition.

Raw Materials

The availability of raw material defines the flourishing status of the boatbuilding industry. The most used raw material for building traditional boats worldwide is timber.

The boatbuilding industry of Goa, traditionally, is also entirely dependent on timber. Goa, being a part of the Sahyadris and Western Ghats, is covered with forest which provides an excellent source of raw material. Boatbuilders get this timber from local sawmills who procure the wood from local forests.

Apart from timber, other raw materials are used. For fastening and sewing, coir ropes or nylon ropes, wooden pegs (*guddi*) (Fig. 3), copper nails, copper rods, stainless steel nuts and bolts, cotton, and cashew oil (*dig*) are required. For caulking a special type of glue is prepared called *cari* by local boatbuilders using local ingredients (Fig. 4) (see Shaikh, 2009, pp. 27, for ingredients and preparation). In order to make sails a cloth called *cori elephant* (a type of cotton cloth) is used. Nylon or cotton rope (*beed*) is used for tying sails. Stone and iron material is used to make anchors.

Tools like hammers, different sizes of saws, and various types of chisels are used (Fig. 5). All the raw materials and tools are locally available in the market except *cari*.

Stages of Boatbuilding

Traditional boatbuilders generally follow systematic stages for building a complex structure (Rajamanickam, 2004).

The boatbuilding process goes through eight different stages.

Selection of Timber

Selection of timber is the first and most important stage. Boatbuilders never compromise while selecting timber on its quality and size as the entire construction depends on it. There is a saying that “the older the timber is, the best it is for its quality”; hence the old is gold. The oldest and best-quality timber well known for its strength and buoyancy is a preferred choice for most Goan boatbuilders. They mostly prefer mango wood (*Mangifera indica*). Jackfruit

Boats in Goa, Fig. 2 “Kharvis,” a fishing community of Goa (Photo: Z. A. Shaikh)

Boats in Goa, Fig. 3 Wooden pegs used for pegging holes made for sewing (Photo: Z. A. Shaikh)

(*Artocarpus integrifolia*) and *Malti* or *Malat* (*Aganosma caryophyllata*) are other preferred timbers. While selecting timber the size of the tree plays a very important role, especially in the

case of dugouts. The size of timber selection depends upon the size of the boat to be built.

Cutting of Timber

Once the timber is selected, it has to be cut into the required shape to form a boat. Nowadays timbers are brought after cutting from the sawmills but traditionally they were cut by saws on a temporary stand (Fig. 6). The bark is scraped with the help of a chisel (*tasni*) and is given a rough square or rectangular shape. This then helps to cut the required size planks required to build the boat or in the case of a dugout the timber is manually dug with a chisel. To cut timber of the required size or to achieve the same sizes of plank marking to cut planks is done with the help of a thread having a coat of charcoal powder, which leaves an impression. This mark is called “level marking” which helps to cut straight timber of equal size.

Seasoning

Traditional boatbuilders place timber and planks shaped from it in a muddy water or backwater for a week, 15 days, or a month depending upon the quality of the timber in the third stage of boatbuilding, seasoning. This is done, as it is believed by

Boats in Goa, Fig. 4 Cari

building traditional boats
(Photo: Z. A. Shaikh)

traditional boatbuilders, to increase durability of the timber and to ease the process of bending planks or scooping the timber to build dugout boats. It is also believed that this makes timber stronger and enhances its resistance against wood borers.

After some days of seasoning, when the timber is ready to use, it is removed from the water and cleaned. Care is taken that the timber after seasoning is not exposed to direct sunlight. This stops the timber from drying and developing cracks which would also make it difficult to scoop it to build a dugout boat. Under soggy conditions digging can be done smoothly and helps to give the proper shape required to build a dugout boat or to give a bend or shape to planks.

Bending Process

After seasoning, the timber is ready to be shaped. In order to form the hull of a boat, planks need to

be bent. One can mostly notice such bent planks at stem and stern side of the boat where the curve shape of the boat is highest (Fig. 7). In Goa this is done by trial and error. First, the exact dimensions of planks are cut. Second, oil locally called kadu oil is applied at the portion of the plank where curvature is needed and the plank is placed above the fire on a temporary stand in such a manner that the distance between the plank and fire is maintained in order to avoid burning. Once the plank is heated on both the sides it is placed where it is required to be fixed and is fastened.

Planking

Planking is a process of adding planks to the boat to extend its size. In Goa, most boats are made of dugouts and planks are added to extend them (see Fig. 22). Depending upon the size of the

Boats in Goa,

Fig. 6 Cutting timber on a temporary stand (Photo: Z. A. Shaikh)

B

Boats in Goa,

Fig. 7 Showing the amount of plank bent in order to form the shape of the hull (Photo: Z. A. Shaikh)

boat, one to three planks are added. Planks are joined either edge to edge or by using an L or V or/shape groove. The edge to edge joint is used to join planks one beside the other that form a strake, while the latter is used to join planks one above the other. While joining plank edge to edge, one plank is joined with the other. In V- or

L-shape joints, male V or L or/groove is made on one plank and female V or L or/groove is made on the other plank; they perfectly fit with each other (Fig. 8). Sometime complex joints are used such as shown in Fig. 9. Such joining of planks seems to check seepage of water and give excellent strength to planks against detaching.

Boats in Goa,

Fig. 8 Male and female V groove joining of planks
 (Photo: Z. A. Shaikh)

**Boats in Goa,**

Fig. 9 Joinery method used to join two planks together to form a strake of plank boat (Photo: Z. A. Shaikh)

**Fastening**

There are two ways that boatbuilders of Goa use to fasten boats: sewing and nailing.

Sewing Sewing is a process by which the planks of boats are fastened by sewing mostly with coir or nylon ropes. Two persons undertake the sewing process: one sitting inside and the other outside the boat. The sewing process starts by drilling holes at the edge of the planks. The distance between each hole is approximately 8 cm. The person sitting inside the boat passes the rope through the holes to the person outside, who pulls the rope very tightly with the help of a wooden stick and passes it to the inside person. The stitch appears X shaped from the inner side (Fig. 10) and I I I I pattern from outer side (Fig. 11). After sewing the holes are packed with wooden pegs.

Nailing Nailing is a process by which the planks of boats are fastened by copper or stainless steel nails (Fig. 12). There are very few traditional boats that have been fastened in this way; they are mostly boats that are plank built and are used for river traffic. In this case the planks are joined one above the other by/groove so that two planks meet each other in such a way that they can be fastened together by nailing. The process starts by drilling the hole at the edges of the plank and nailing along the strake with the help of a hammer.

Caulking

Caulking is a process by which boats are made waterproof in order to avoid any leakage. It is done while fastening planks as well as after fastening them. While fastening planks, caulking is

Boats in Goa,

**Boats in Goa,**

Fig. 12 Plank boat fastened by copper nails (Photo: Z. A. Shaikh)

Boats in Goa, Fig. 13 Illustrating caulking while fastening or sewing the plank boat (Photo: Z. A. Shaikh)

done with the help of cari or tar and cotton. Before joining the planks, cari is applied on the edges of planks and cotton is placed on top of cari and then the planks are placed against each other, ready for sewing. The gap between the two planks is filled with cotton and secured with the help of tar (*dambar*). This is then covered with dried coir and coir rope and sewn (Fig. 13). Such caulking acts as a barrier for any seepage of water inside the boat through the little space that might have been caused due to any uneven surface at the edges of planks left during joining.

Caulking of planks is also done after fastening planks or once the entire boat is built. This is done by applying cashew oil (*dig*) outside of the boat. If there is any hole or leakage noticed, it is filled with *lambi*. Lambi is a type of glue prepared by local carpenters by mixing cari and *chunnam* (calcium carbonate) together that act as a filler.

Outside Treatment

Outside treatment is given to a boat in order to avoid damage to the timber by wood borers and to increase the longevity of the boat. Such treatment also serves as secondary caulking. It is done by

applying oils such as Kadu oil or cashew oil on the inside as well as the outside of the boat (Fig. 14). This is applied regularly after 15 days or 1 month or 3 months. In Goa November and December are the months preferred for this treatment. Nowadays varnish paint is also applied. Two or three strips of different colors are painted, especially on the bow side. This helps in identifying the owner of the boat. A fiber coat is applied to most of the boats as it remains permanent and prevents damage by borers.

Boat Types and Building Techniques

There are several types of boats which are generally classified on the basis of their construction pattern, size, and shape (McGrail, 1996; Rajamanickam, 2004). Traditional boats in Goa consist of the following types.

Skin Boats (Coracle)

Skin boats are locally called *harigolu*. They (Figs. 15 and 16) are made of bamboo strips or canes. Bamboo stripes are woven together to

Boats in Goa,

Fig. 18 Diagram illustrating a proportionate thickness maintained along the gunwale in order to maintain the buoyancy of the boat while in water (Illustration: Z. A. Shaikh, 2011)

form a circular shape, and thus they appear like a wide circular basket. Their height varies from 30 to 40 cm and width from 1.5 to 2 m. They are then waterproofed from outside by covering them with plastic or polythene sheets. A coat of tar is applied on top of a sheet which checks water seepage into the coracle. These boats are very flexible and light weight, and as a result they can be carried to other places. They are propelled by paddles. Such boats are mostly used for fishing in calm inland waters.

Dugouts (Logboats)

Dugouts or logboats are locally known as *ponjal*, *ponyao*, or *vodem*. These boats can be subdivided into two types: dugout without outriggers and dugout with outriggers. Outrigger is an additional component provided to enhance balancing.

Dugout Without Outriggers

Dugouts without outriggers (Fig. 17) are built by hollowing a single log of timber with the help of a chisel. They are mostly built of mango timber that is seasoned in the backwater. Once ready, the timber is given a rough shape and hollowed by scooping until the required shape is achieved. While scooping, boatbuilders see to it that there is a proportionate thickness maintained along the gunwale in order to maintain the buoyancy of the boat (Fig. 18).

After scooping, the log is made smooth with adzes and chisels. Sometimes frames are carved while scooping or else added afterwards for strengthening. Thwarts are fixed to gunwales in a groove on the gunwale plank by making L-shape angles on four corners and tying with nylon rope (Fig. 19). These thwarts provide

space for sitting. After completion of construction, cashew oil is applied to the entire boat. To build this type of boat, it takes approximately 20–30 days.

These boats have an elongated look with V-shape vertical cross sections at the bow and stern and U-shape vertical cross sections in the middle. Their bottom is usually flat and thus mostly used in calm waters for inland fishing. Oars propel such boats.

Boats in Goa, Fig. 19 Fixing a thwart on the gunwale by making L-shape joints on four corners of the thwart (Photo: Z. A. Shaikh)

Dugouts with Outriggers

These boats are built in the same way as dugouts without outrigger. There is no difference except that in these boats the outrigger is fixed and sometimes a keel is added. These types of boats make them seaworthy and are mostly used in estuaries or near shore zones with an additional balancing aid provided by an outrigger. The outrigger is made up of a log, shaped as a boat, and attached to the boat with the help of two bamboos (see Fig. 22 where extended boat has outriggers attached).

Extended Dugouts

There are three subtypes of extended dugouts. They are extended dugouts without outriggers with 1 stroke (Figs. 20 and 21), extended dugouts with outriggers having one to three strokes (Figs. 22 and 23), and extended dugout with outriggers having mostly three strokes locally called Rampon boats (Figs. 24 and 25).

Boats in Goa, Fig. 20 Side view of an extended dugout without outrigger with 1 stroke (Photo: Z. A. Shaikh)

Boats in Goa, Fig. 23 Top view of an extended dugout with outrigger having 1 to 3 strakes (Photo: Z. A. Shaikh)

Extended Dugouts Without and With Outriggers

Extended dugouts without outriggers (Figs. 20 and 21) and with outriggers (Figs. 22 and 23) are locally called *vodem* or *hodi*. These types of boats are built by fixing one or two rows of planks

(strakes) on either side of a dugout boat along the gunwale. They go through the same process as building a dugout. Once the dugout is built, it is extended from both sides by placing one to three strakes.

Strakes are joined along the gunwales by giving a slope shape (/) cut to the upper edge of the gunwale of the dugout and to the lower edge of the plank to be fitted. The planks that form a strake are joined to each other by male and female V grooves. Strakes are mostly fastened by sewing. While planking, caulking is also carried out. This means that while joining the planks *cari* (glue) is applied on the edges of planks and cotton is smeared between the planks to be joined and sewed together.

These boats are sewed together mostly with nylon ropes, but some with coir rope, through the holes, opposite to each other, which are made at a distance of 6–8 cm between two strakes and at a distance of 19–20 cm on each plank, beside each other, along the edges of a strake. Wooden pegs used to fix the holes made for stitching are dipped into cashew oil before pegging.

Once the outer shell of the hull is built, frames of U shape are added with copper rabbet. They are mostly carved and thus made of a single timber. Before the topmost strake is fixed, thwarts (horizontal plank within the hull) are fixed between the topmost strake and the following strake. They provide horizontal support to the

B

Boats in Goa, Fig. 24 Side view of an extended dugout with outrigger having mostly 3 strakes locally called Rampon boat (Photo: Z. A. Shaikh)

Boats in Goa, Fig. 25 Top view of an extended dugout with outrigger having mostly 3 strakes (Photo: Z. A. Shaikh)

hull. Thwarts are basically used for seating by crew members.

Finally the keel is added at the base. The keel is prominent at the base of the dugout; it merges when it reaches the bow and stern. If the keel is made of 2 timbers, it is joined by making male and female V grooves. Once the keel is fixed, cashew oil is applied to the entire boat to protect it from woodborers as an outside treatment. The construction of this boat takes 1 or 2 months depending upon the size of boat.

These boats are mostly used offshore and at very few places along the riverside. They are propelled by oars and sails, but now in some localities motorized engines and rudders are

used, mostly for sea fishing. At some places these are used for bringing firewood from local islands and for ferrying.

Extended Dugouts with Outriggers (Three to Five Strakes) Rampon Boat

The Rampon-type boats (Figs. 24 and 25) are known as *Ramponachem vodem*, and they are differentiated from the above two types not by their construction but by their size, hull shape, and use. These boats are built by extending dugout boats which are much narrower than the dugouts used to build the abovementioned boats. These types of boats are found along every beach of Goa and are only used for fishing locally

Boats in Goa, Fig. 26 Top view of plank-built boat (Photo: Z. A. Shaikh)

called Rampon fishing. The difference between an extended dugout with one to three strakes and a Rampon boat is that the former has an almost U-shape cross section and the latter almost a V shape. That means Rampon boats are narrow at the bottom and wide at the top. This provides extra space to keep huge nets.

The building technique of this boat is similar to that of extended boats. Generally mango wood is used for construction. Once timber is selected, it is seasoned and scooped. The dugouts which are used as a base for these types of boats are narrow. In these boats two to five rows of planks are joined on the dugout. While joining planks, caulking is done on both the inside and outside. The planks are fastened by sewing with coir rope.

Frames, made of two pieces of timber, are fitted at two places where the outrigger posts are fastened. Thwarts are also added and are fastened between the topmost and the following strake. Once the outer hull is ready, a keel made up of three pieces of timber is fitted by making male and female V grooves and sewing them with coir or nylon rope. An outrigger made of bamboo and heavy timber is added to the boat. Dig is applied to the entire boat. These are mostly used for nearshore fishing. These are propelled by oars but sometimes a rudder is attached to them. This boat takes almost 1 or 1½ month for its construction.

Plank-Built Boats

These boats are locally called *Revechem hode* (Figs. 26 and 27). There are two types of plank-built boats: sewn and nailed plank-built boats. These boats are mostly made of Malat timber. Two to four persons are involved in the construction. First, the keel is laid. Three pieces of timber are used which serve as the main keel, bow keel, and stern keel. The stern keel and bow keel joined to the main keel by using a joinery or interlocked method as shown in Fig. 28. Such interlocking helps against the dislodging of bow or stern keel from the main keel.

After laying the keel, six to eight rows of strakes are added to form an outer shell of the hull. These strakes are added in such a way that the vertical section in the middle becomes U shaped whereas the bow and stern become V shaped. Planks are fastened either by sewing or by nailing. Frames are made of three pieces of timber and are joined by using various joineries as shown in Fig. 29. In the middle an iron rod is provided horizontally for strengthening the hull. Frames are fixed at 120 cm distance and fastened with coir rope. Once frames are fastened, thwarts are added with coir ropes at varied intervals. The gap between bow and first thwart is about approximately 332 cm, and the distance between other thwarts to the stern is approximately 120 cm. A platform is created between bow and the first

Boats in Goa, Fig. 27 Side view of plank-built boat (Photo: Z. A. Shaikh)

Boats in Goa, Fig. 31 Terms used for Different parts of boat (Photo: Z. A. Shaikh)

thwart and the stern and the last thwart where steersmen called *tandel* can sit. Cashew oil is applied to the entire boat.

A rudder is added at the stern of the boat. Since these boats are used only for short distances to carry river sand, they are not operated by oars or machines. Long bamboo sticks are used as poles, and sometimes sails made of plastic sheets are used. It takes almost 1½ or 2 months to build this boat.

Distribution of Traditional Boats of Goa

Geographical features and oceanographic and seabed conditions determine the distribution of traditional crafts (Fig. 30). In Goa the most dominated traditional boat is the Rampon boat. Dugouts without outriggers are found mostly along the major rivers and their tributaries, and dugouts with outriggers are found all along the estuaries, coastline, and in rivers where the water is comparatively rough with high currents. Extended boats without outriggers are found mostly along the beaches of Goa which are engaged in minor fishing. Extended boats with outriggers having two or three (2/3) strakes are found all along the Goa coast and are suitable for long-distance sea fishing. Sewn plank-built boats are found mostly along the rivers.

Different types of traditional boats have been observed along the coast of Goa but Rampon stands as a unique type in the history of boatbuilding technology. The traditional boatbuilding industry is strongly backed by the basic knowledge of local craftsmanship which is passed on from father to son. Boats in Goa, therefore, are a living heritage that can provide an important insight into the ancient boatbuilding technology (Fig. 31).

Acknowledgments I would like to thanks Dr. Lucy Blue (University of Southampton), Dr. Sila Tripathi, and Dr. Vasant Shinde (Deccan College, Pune) for sharing their knowledge and inputs toward this topic. This work would not have been possible without the help from boatbuilders and fishermen of Goa who allowed access to their boats for recording.

Boats in Indonesia

Aziz Salam
University of Gorontalo, Gorontalo City,
Indonesia

The presence of boats, or the prahu, in Indonesia is as old as human existence in the archipelago. When early humans inhabited the caves, boats were part of their lives. Some of those caves illustrate prehistoric boats that may have been used by those who painted them or perhaps by their ancestors of several prior generations, the Australo-Melanesians who migrated from Sundaland to Wallacea, the islands beyond, in search of new livelihoods. There is a report of a boat painting in caves of the Little Kei Island in eastern Indonesia. Reproduction of the cave imprint presented by Intan (1998) shows the boat as a dugout with additional structure and projecting bows. This painting resembles the boat painting with pictures of men, animals, and the sun along with pictures of long boats called *kora-kora* found in East Timor reported by Ruy Cinatti in 1963. All those boats were single-bodied dugout canoes without outriggers, although some of them show additional construction for poles and sails or other strengthening structures (Fig. 1).

Outrigger canoes are absent from cave paintings. The outrigger boat technology is associated with the second wave of migration of Austronesians from Taiwan to Indonesia circa 2000 BCE, who brought more advanced technology than the Lapita civilization had in the eastern part of the archipelago. They might have started life in pillared houses above sea level or on their stable boats that roamed the waters before they reached Madagascar in the ninth century and spread to Polynesia until they reached Hawaii and New Zealand in the tenth century.

From the early centuries of the first millennium, the Strait of Malacca, the only passage that connected the West and the East at that time, witnessed the passing of foreign ships. Trading and envoy sending between China and India,

Boats in Indonesia, Fig. 1 A prahu painting on a cave wall in Ohoidertavun Village in Lesser Kei Island (Intan, 1998)

Persia, Arabia, and Rome made the Strait a busy center of traffic. The latest archaeological findings in many places along the Strait of Malacca shipping lanes and Java Sea affirm this. Chinese historians wrote about the sea-going vessels known as *Kunlun-po* in the third century. The ships of the *Kunlun* are described as extending to 200 ft in length and standing out of the water up to 20 ft equipped with up to four obliquely mounted sails. The presence of foreign boat technologies is very influential to the development of indigenous boats in the archipelago even to this day.

The oldest evidence of outrigger boats is preserved on the impressive reliefs of the eighth-century Borobudur Temple. However, the earliest written description is found in the fifteenth-century *La Galigo* cycle, the world's longest epic manuscript written in the royal court of the Bugis-speaking Luwu Kingdom. The boats are described as aristocratic boats used in adventures and wars to conquer neighboring states. A story in the *La Galigo* that narrates the creation process of the mythical boat of the protagonist by "godly creation" indicates that the boat's body consisted only of a large tree that is hollowed out, a dugout boat. Further detailed descriptions say that they were ocean-going outrigger boats with a deckhouse structure, tripod mast, squared sails, and lateral rudder. Borobudur's ocean-going outrigger ships with additional side planks above the outrigger level were certainly dugout boats because only dugout boats with outriggers to balance because of breadth limitation restricted by the diameter of the wood log could have been used. And the side

Boats in Indonesia,

Fig. 2 A relief of a sea-going outriggered ship on the wall of Borobudur Temple

planks formed the upper structure to increase seaworthiness and thus carrying capacity. The tripod mast construction on a La Galigo boat is like the Borobudur ship but with additional technical details such as that their masts recline in the off-sail state. Borobudur reliefs were permanent poles with ladders to climb. This and the addition of the superstructure indicate that Borobudur boats were bigger than the La Galigo boats (Fig. 2).

Interestingly, the kingdom of Majapahit in the book of *Negarakertagama* written by Prapanca in 1364 claimed all known states in Sulawesi as its vassals. There are two possibilities as to what type of boat was used by Gadjahmada, the prime minister and commanding general, in conquering the eastern archipelago. It is not certain whether the fleet utilized the Borobudur boat technology or the plank boat technology which must have already existed. The first possibility is associated with the presence of outrigger boats in the eastern part of the archipelago at nearly the same time or after the conquests. The outrigger boat is still in use today by small-scale fishermen across the archipelago. Hundreds of local names are used all over the country with variations in their appearance and parts. A. C. Haddon and James Hornell documented the outrigger and dugout in their *Canoes of Oceania*. One remarkable type of outrigger is the sailing *sandeq* of Mandar. The *sandeq* has developed in size since the 1970s, and in 1990, its average length was about 7–8 m. At present, the *sandeq* that sails the

open seas for fishing activities is more than 10 m long, and the dimensions would be optimized if the *sandeq* is used for racing. There are at least three variations within the *sandeq* type depending on its usage in fishing. For flying fish fishing there is the *sandeq potanga*; for fishing at *roppong*, which is a fish aggregating device, there is the *sandeq paroppong*; and for daily-short-distance fishing, there is the *sandeq pangoli*. The second possibility is attributed to the story of the origin of Lamaleran. The story goes that local oarsmen (probably the sea nomads) were sent further east and reached the Aru Islands. The small fleet went south round the back route to the west and experienced calamity, and the survivors then occupied the shores in Lembata Island. The current boats of plank technology in Lamalera, which is the remnant of their ancestor's wrecked ships, are very similar to the most basic plank boats in South Sulawesi, the *pajala* hull (Fig. 3).

A common characteristic of traditional plank boat construction in various ship-building centers in the archipelago is the backbone structure. The backbone is a solid structure that bears the longitudinal strength of a boat. The structure comprises the keel, the keel extensions, the stem- and stern-posts, and the strengthening clampers fixed on both sides at a length that covers the joints between the keel and its extensions. The plank pattern is also similar, and thus, the hulls are similar in form. The *pajala* and the *patorani* of Makassar, the *leti-leti* of Madura, the

Boats in Indonesia, Fig. 3 A sandeq for fishing

mayang of Sunda Strait, the *baqqoq* of Mandar, the *pencalang* of Java, and the *pledang* of Lamalera all share the basic hull form of what Adrian Horridge called the *pajala* hull. These are the earliest planked boats operated in the archipelago with an open hull structure (without fixed and watertight decks) with smooth curvature seen from any perspective. The plank pattern of the *pajala* hull, as Horridge observed, suggests that it is not far removed from the traditional boats of 1,000 years ago. The stem- and stern-posts are joined end to end with the keel to form a smooth continuous curve, although the bottom is flat with a negligible projecting keel. Bows and sterns are similar in shape, often turning in at a sharp angle because the planks are carved, never bent, to shape.

A Portuguese account written by Tome Pires in 1512 mentions a type of boat called *pangajavas*, which he encountered in Palembang and along the north coast of Java. Pires encountered the Bugis on their “large well-built *pangajavas*” in the port town of Malakka and learned the name *pangajava*, which means “a ship that frequents Java Island.” This nomenclature is common in Sulawesi to name a type of ship based on the place it most frequently visits or the commodity it commonly catches or the fishing gear it uses. Pires then gave the name *pangajava*

to all the planked boats or ships with lateral rudders and square sails, the common characteristics of all native trading ships of Indonesia at that time. Pires might have seen, in the ports of Java, the *pencalang* type, and the “large well-built *pangajavas*” might be the Makassar *biseang* used for overseas fishing and trading in that era. He described the Bugis from “Macaçar Island” as respected traders who frequented many places with their boats to Pahang and Siam and the countries between the two and Malacca, Java, and Borneo (Fig. 4).

After the conquest of Makassar by Speelman in 1669, he reported in his *Notitie* the existence of the Bajaus in Spermonde Islands who “travel to all islands laying further out to sea, to gather tortoise-shell from them, which they are obliged to deliver to the King of Makassar; and moreover they must always be ready to go with their vessels in any direction they are sent, wherever the King from time to time sees some advantage.” The gathering of trepang and tortoise shell to supply the Chinese market at Makassar continued to the eighteenth and nineteenth centuries, and other ethnic groups joined in as they saw profit in it. They used to go as far as Dewakang Island far south of Makassar when the resources depleted at nearer locations, and they eventually roamed the northern coasts of Australia. Captain

Boats in Indonesia, Fig. 4 A prahu pencalang (a) of the Mid-nineteenth Century (Horridge, 1986) and a Makassa trading prahu (b) (Horridge, 1985)

Boats in Indonesia,

Fig. 5 Drawing made in 1803 by the artist William Westall of a Bugis prahu on the Arnhem Land coast (Horridge, 1985)

Matthew Flinders of H. M. S. Investigator met with a fleet of the *trepangers* (the *paqtaripang*, a specific type of *paqdewakang*) in 1803. In February 1840, Lieut. Owen Stanley on board H.M.S. Britomart sketched praus, which were part of a fleet that annually fished the waters off Arnhem Land for trepang. In 1818, Phillip Parker King, an Australian hydrographer, encountered similar prahus with double tilted sails (Fig. 5).

The hull construction of a trading *paqdewakang* is similar to the hull of a *paqtaripang* except that the first is larger in size and it has additional upper structures. This is the

type of boat boarded by Alfred Russel Wallace in his voyage from Makassar to the Aru Islands in 1856. He described the prahu as

It was a vessel of about seventy tons burthen, and shaped something like a Chinese junk. The deck sloped considerably downward to the bows, which are thus the lower part of the ship. There were two large rudders, but instead of being placed astern they were hung on the quarters from strong cross beams, which projected out two or three feet on each side, and to which extent the deck overhung the sides of the vessel amidships. The rudders were not hinged but hung with slings of rattan, the friction of which keeps them in any position in which

Boats in Indonesia,

Fig. 6 Paqewakang model
(Rotterdam 29568) in
Horridge (1985)

they are placed, and thus perhaps facilitates steering. The tillers were not on deck, but entered the vessel through two square openings into a lower or half deck about three feet high, in which sit the two steersmen. In the after part of the vessel was a low poop, about three and a half feet high, which forms the captain's cabin, its furniture consisting of boxes, mats, and pillows. In front of the poop and mainmast was a little thatched house on deck, about four feet high to the ridge; . . .

The ship had two masts, which were movable tripods, a system that persisted since its use on the La Galigo boats. The sail carried by this vessel was an oblong shape just like the ones encountered by Captain Flinders half a century earlier. The sail was hung out of the center so that when the short end was hauled down on deck, the long end mounted high in the air. The foresail was of the same shape but smaller. Both were of matting and with two jibs and a fore and aft sail astern of cotton canvas (Fig. 6).

The *paqewakang* type declined in number from the 1860s onward. A new schooner type called *pinisi* emerged. The name resembles the names of European ships: the Netherland *pinas*, the British *pinace*, and the French *peniche*. In 1935, G.E.P. Collins had the local people from Bira village build a *palari*-type schooner which had the initial hull form of a *pinisi*. A change in the hull size and the adoption of a schooner rig

system on a *paqewakang* turned the ship into a *palari*, a name which literally means “runner” or “racer” owing to the improvement of its sail and rigging that makes it speedier. The idea was to increase the carrying capacity of the former trading ship by raising the hull sides and to increase speed by implementing a new schooner sail and rigging system. By raising the hull sides, the main deck became higher than the traditionally maintained stern- and stern-post level. This problem was solved by constructing *ambeng dua kali*, which are double platforms hanging under one another at the stern and at the aft by making the splashboard a wall the height of the main deck (Fig. 7).

A picture of Makassar Port in 1920 reproduced in a photo book (Scarpello & Makhfudz, 2004) from a photograph in KITLV-Leiden shows tens of *palari* at anchor among other ships with Western hulls. This picture suggests that further advancement of the *palari pinisi* into the famous *pinisi* of Bugis-Makassar in its latest form of hull had not yet taken place. The *palari* building by Collins in 1935 and the folk story about the existence of *pinisi* in the early 1940s in Spermonde Archipelago might lead to the conclusion that *pinisi*, the summit of sailing *prahu* evolution in Indonesia, most likely took its last hull shape in the late 1930s. Again, the principal difference

between the new modification and its preceding types was the carrying capacity as was necessitated by the ever-increasing volume of trade. As the hull became bigger and taller, the stem- and stern-post problem could no longer be solved conventionally as in the *palari*. The stem- and stern-posts in a *pinisi* are lengthened up to the deck level, and the upper side planks are extended to be fitted to the posts at the center line. This modification thus eliminates the splashboard

Boats in Indonesia, Fig. 7 The *palari* built by G. E. P. Collins at Bira Village in 1935

and the void space between it and the stem-post and makes the hull a complete round vessel. This requires the stem-post to be a little far away from the points where the upper side planks start to bend sharply inward, resulting in the forward-leaning stem-post of the *pinisi*.

Adrian Horridge describes the *pinisi* in his book *The Prah*. The *pinisi* are partly a copy of a western schooner of the mid-nineteenth century, ranging in size from 120 to 200 t. They are recognized by their tall ketch rig of seven sails, including two topsails, three jibs with bipod or tripod foremast, and fixed gaffs. The enormous, heavy bowsprit with crossbeams and lateral boards is strengthened to support three jibs and a powerful forestay, which runs over both masts. The two lateral rudders are supported on a group of heavy beams, which run right through the stern. The deckhouse and upper part of the stern (*ambeng*) were added over an enlarged *pajala* hull (Fig. 8).

The motorized sailing prahu was the next transformation. The motorized *pinisi* emerged in the 1980s when the traditional *pinisi* fleet, the so-called *pelayaran rakyat* or people's shipping, was encouraged to adopt motorization. The superstructure of a motorized *pinisi* occupies half of the deck length, leaving only the foremast. There are only five sails: a main sail, a topsail, and three jibs. The engine requires a significant

Boats in Indonesia, Fig. 8 A replica of a *pinisi*

Boats in Indonesia,

Fig. 9 Motorized wooden ship now dominates shipping in Indonesia

B

adjustment in the aft buttock to accommodate the engine foundation, the propeller and center rudder installations, and the engine room. Moreover, the next development resulted in an entirely new type of wooden ship, the motorized ship. Its hull is entirely of western type, and there are no more sails even for auxiliary power. The mast is now decorated with motor-powered lifting booms for loading and unloading operations (Fig. 9).

Not much is known about the evolutionary development of other boat types in Indonesia except that all types of traditional boats in the 1980s were touched by government programs of motorization. Motorization gave the final blow to the indigenous boats when they were required to adopt the western hull style halfway or totally. The backbone construction of a western hull, as opposed to traditional hulls, consists of straight pieces of wood. Joints are made at clumsy angles, which look to be stiff. The construction is built with three parts: the keel, the stem-post, and the stern-post. To put an engine inside a traditional hull would require some construction reformation, such as a strong structure for the engine foundation, centered propeller and rudder installations, engine rooms, and wheel rooms. The traditional accommodation for the crew inside the hull became inconvenient because of

engine installation, and crew cabins were built on deck behind the wheel room. Now, as the propelling function of the sails is largely replaced by the engine, the number of masts and sails are reduced in certain types and totally dismissed in other types.

Boats in Vietnam

Charlotte Minh Hà Pham
Asia Research Center, Murdoch University,
Murdoch, WA, Australia

The Vietnamese coastline, with long beaches exposed to the surf, deep bays shadowed under high capes, idyllic coves sheltered from the monsoon winds, and numerous river mouths, abounds with an incredible diversity of boats. Stretching

over 3,440 km, from latitude 21°N to latitude 8°N, the environment changes from north to south and so do the people, their sociocultural contexts, their politico-economic history, their maritime activities, and their related boats. Each port, coastal town, and bay had its own fleet of boats, which traditionally differed from one another. Rigging, helm, hull decoration, or hull shapes varied from island to coast, from bay to cove, from fishing town to trading harbor. A few main types that still survive now will be described here to illustrate this diversity and to highlight the skills and originality of Vietnamese boatbuilding, past and present.

Archival material, postcolonial studies, and contemporary research on the boats of Vietnam (Pham, 2015a, b; Pham, Blue, & Palmer, 2010) together provide an excellent boat record to draw upon to characterize the different boat types and the main patterns of construction and to also document some of the technological changes that occurred in boat traditions across time (see Pham, 2013 for a broad historical overview). During the lifetime of the first emperor, Gia Long (1762–1820), a few French-style ships were constructed (Mantienne, 2003), but, overall, the traditional constructions and the wide diversity of traditional boat types were maintained with barely any Western input until the 1940s as shown in the studies of Pietri (1943), Paris (1942), or Poujade (1940). Traditional sailing boats still plied along the coast until the mid-1960s, as attested by the American Blue Books (1962, 1967), but from then on, diversity started to fade. New materials (plastic, nylon, aluminum) and the introduction of small diesel engines were the key elements causing this change. Sails disappeared, but some shapes and features inherited from the traditional sailing boat types are still discernible in present-day boats, such as the generic double-ended shape of the sailing boat hull (Fig. 1) and *oculi* (eyes to guide the boat and scare sea monsters) or some unique features specific to the boats of Vietnam such as the *ngà* (cathead carved and painted embodying the soul of the boat), the sliding bow board (anti-leeway device), and the hulls made out of basketwork.

Boats in Vietnam, Fig. 1 Traditional working wooden boats anchored in the bay of Mui Ne (Binh Thuan province) (© C. Pham 2013–2014)

Since the late 2000s, fewer boats are being constructed in the traditional way. Government regulations (i.e., *chỉ thị 16 năm 2009* and *quyết định 48 năm 2010*), promoting the development of distant seagoing fleets to protect the depleted coastal ecosystems, mark a major change in the practice of fishing and therefore of boat use and construction. Nowadays, vessels using engines over 30 HP are under strict control and soon traditional wooden boats will not be constructed anymore. This is one of the biggest changes in the boatbuilding history of Vietnam and implies in the long term the total loss of traditional boatbuilding.

The Modern-Style Vietnamese Boat

Nowadays, the most noticeable boat style, representative of the contemporary Vietnamese modern boat, is constructed according to a licensed and regulated government-approved plan that completely breaks with traditional boatbuilding.

It is built frame first, based on a heavy keel timber, instead of plank first (Fig. 4). Floor timbers are bolted to the keel, and curved futtocks

are fastened to the floors with bolts and nails. Compared to the slender shapes of the sailing vessels, the modern hull is imposing with a broad beam, almost boxy (the further south, the boxier it gets), a nearly vertical tall stem cuts the water, and ends with a counter stern with a large flat transom. A 250–300 HP engine is located at the heart of the boat, under a large pilot house aft. Aft of the house, the rudder shaft passes through the keel, behind the propeller. Forward of the house, there are large holds for storing fish and ice. The foredeck is long to fit the gear for squid fishing (with many rows of lights in racks on either side and long booms for spreading nets at night) or for hauling large nets (Figs. 2, 3, and 4).

The modern-style boats exist in various sizes that vary between 11 and 30 m but tend to an average of about 14–16 m. They are manned by about 12–20 sailors/fishermen. Crews sometimes spend weeks offshore, at the Paracels and the Spratlys, or several months as far distant as Malaysia.

There is no specific name to identify this kind of boat. They can be referred to simply as *tàu* (ship), *phà*, or *ghe phà* (boat mix) or have regional names, depending on the size, the place

Boats in Vietnam, Fig. 2 Large modern-style boat set up for squid fishing (Khanh Hoa province) (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 3 Medium-sized modern-style boat, manned by 5–7 crew and coming back from a day of fishing 7–8 nautical miles away. Larger boats in that

region fish in the area of Phu Quy and Con Son islands (60–130 nautical miles away) (Binh Thuan province) (© C. Pham 2013–2014)

of origin, or the type of fishing they conduct such as *ghe bò gù* in Phu Yen, *ghe mảnh ghép* in Binh Dinh, or *ghe đà cao*, *ghe lưới rút*, and *ghe chài* in Binh Thuan. None of these names are fixed.

Many of these boats are painted bright blue (sometimes gray or green) with a red trim and white cabin window outlines. In the southern provinces of Ninh Thuan and Binh Thuan,

B

Boats in Vietnam, Fig. 4 All the modern boats are now constructed frame first and have a counter stern with transom and an upright stem (Ninh Thuan province) (© C. Pham 2013–2014)

however, they tend to be dark, the natural wood only covered with layers of *dầu rái* (oleoresin), and highlighted with a yellow top wale (Fig. 3). All have at their bow a neatly painted registration number but they do not have the *oculi* of traditional boats. Naturally, a few differences occur regionally, most particularly depending on the type of fishing they conduct, but the regulations are strict and scrupulously followed by the younger generations of boatbuilders.

These characteristics are common to all the modern boats along the coast which can easily be spotted in fleets of hundreds in the main ports and harbors of the country (Fig. 5).

Transition Boat

Among the fleets of modern boats moored in the harbor basins, a smaller boat type with a sharp bow but flat stern can also be noted. This boat, usually called *ca nô* or sometimes *ghe gió lượn* embodies the technological transition between the sailing boat and the modern boat with engine, which seems to have occurred mostly after the American War. The *ca nô* retains some

traditional design elements which were adapted to motor power. The hull shape is still long and slender, with a high overhanging sharp bow directly descended from the traditional sailing boats, but the stern is not pointed and runs to form a flat transom. This is because of the placement of the engine, which was initially fitted aft on the old sailing boats, in a small engine house. The fishing appendages are fitted on the foredeck, where sometimes the remnants of a mast serve to hang up lights for squid fishing or a protective tarpaulin. The bow is decorated with traditional *oculi* and with a *ngà* (cathead). These boats reach a maximum of 15 m and usually fish near the coast staying at sea for a day or two, with a crew of two to five fishermen (Fig. 6).

Traditional Boats: General Characteristics

The wooden working boats that survive in the present day and that descend from the traditional sailing boats can be categorized according to their hull construction. Some hulls in a northern tradition have planks edge-joined by nails, on a

Boats in Vietnam, Fig. 5 Fleet of modern boats (Binh Dinh province) (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 6 *Ca nô* of Phan Ri. Note the small *oculi*, the cathead, and flat transom (Binh Thuan province) (© C. Pham 2013–2014)

keel plank that rises fore and aft and ends with a flat transom. Hull planks in the center and south of Vietnam are edge-joined with dowels and have high sterns and prows overhanging the water. Other hull planks were stitched, and some bamboo rafts were fitted with sails and daggerboards. Yet, the tradition that is the most particular to Vietnam is the bamboo-basket boat tradition. It is a construction technique that is unique although

sometimes compared to *coracles* or *kouffas*, with which the small round basket boats share their shape. The bamboo-basket tradition however is technologically different from these, and above all it stands out for its wide variety. From small round boats to large 15–20 m seagoing surfboats, sizes, shapes, and uses are numerous. Nowadays, these basket boats are still ubiquitous in Vietnam (although not in large sizes anymore).

Boats in Vietnam, Fig. 7 Foot rowing: the rower locks each foot to an oar and faces the direction of the route (Binh Dinh province) (© C. Pham 2013–2014)

Overall, traditional sailing boats in Vietnam, including large sailing basket hulls, were mostly operated along the coast, for trade or fishing. In general the length did not exceed 20 m. The tonnage of the larger class of seagoing sailing vessels ranged from about 20–120 register tons (although some historical references say there were more). Sail types could roughly be differentiated from north to south; however sail type is not a reliable indication of a vessel's origin because sail types can easily be adopted outside their area of origin. Traditionally, the most common shape was a lug sail, rigged on one to three masts that could be lowered even at sea.

In the north, the sails were often of the Chinese junk type, of cotton cloth, with bamboo battens laced to the sail. In the center of Vietnam, the lug sails were quadrilateral and made of woven palm leaves, while in the south, they were closer to triangular. Further southwest, near the Gulf of Siam, their shape was quadrilateral.

Small boats (up to 7 m) were mainly propelled by oars. In Vietnam, north or south, the rower faces forward, whether using crossed oars or one long sculling oar or when rowing with his/her feet which is also a particular Vietnamese technique seen in several provinces (Fig. 7). Steering devices, rudders, fishing gear, color schemes, and decorations also varied regionally.

Today, if large boats tend toward uniformity, diversity still survives in the small boats used as harbor taxis, harbor carriers (ice, water, and other supplies), fish buyers, riverine and inshore coastal fishing boats, and small canoes operated

on the canals and lagoons. From being simple smaller versions of larger boats to having features of their own, they mix various characteristics, exist in various shapes and sizes, and are made from various materials or combinations of materials (wood, bamboo, and nowadays galvanized steel sheets, aluminum, fiberglass, and plastic) (Figs. 8, 9, 10, and 11).

Introduction to Representative Traditional Boat Families

Basket Boats

The basket hulls are composed of a bamboo mat woven with bamboo poles that are split in long laths of about 3 mm thickness (length depends on the shape and size of the boat). First the bamboo mat is woven, and then it is given its shape by being laid into a pit or fitted within a bamboo structure and then clamped within bamboo gunwales (Figs. 12 and 13).

The hull is then covered with a sealing material, inside and out. Traditional recipes include first a layer of buffalo or cow dung and then two or three layers of *dầu rái*, an oleoresin extracted from *Dipterocarpus* trees in central Vietnam. In the north of Vietnam, a lacquer resin was extracted from the *Rhus succedanea* L. tree and mixed with sawdust (Aubaile-Sallenave, 1987). Nowadays, some boatbuilders use tar or cement, the lacquer resin being very expensive and dangerous to use (Burningham, 1994, pp. 233–234). Gunwales, topside wooden planks, thwarts,

futtocks and floor timbers, and stringers of wood or bamboo can then be fitted within the bamboo hull to reinforce the structure (for full construction sequences, see Amos, 1997; Bui & Girard, 2007; Pham, 2012; Tallec, 1997).

The most noticeable and most common basket boats are the small round ones generically called *thuyền thúng* (Fig. 14). Some can be as small as 1 or 1.5 m in diameter, maneuvered only by the sculling movement of a paddle or, even without a

Boats in Vietnam, Fig. 11 Small aluminum canoes retaining the shape of bamboo-basket canoes (Ninh Thuan province) (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 12 Preparation of a bamboo-basket hull. The bamboo mat is laid in a preformed pit. The long green bamboo pole split in two will “sandwich” the rim of the bamboo mat to form the wales (Quang Ninh province) (© C. Pham 2010)

paddle, the boatman moving the boat by thrusting his legs and recovering while holding onto the rim. Some can carry three to four passengers or sometimes many more in calm water in harbors

Boats in Vietnam, Fig. 13 The bamboo gunwales clamp the bamboo mat, which is fastened with fence wire (Quang Ninh province) (© C. Pham 2010)

or near the shore. Some are larger (3 m) and deeper with a long-tail outboard motor engine and operated by one fisherman, who goes one or two nautical miles offshore. Other basket boats, almost round but with a stem and sternpost and fitted with a 24 HP diesel engine, go fishing 10–20 nautical miles offshore and reach about 7 m in length. They are called *thúng xoài* or *xoài máy* because their shape resembles a mango (Fig. 15).

Boats in Vietnam, Fig. 14 A small round bamboo-basket boat, *thuyền thúng*, fitted with a long-tail outboard motor and maneuvered by one fisherman, can go fishing

1 or 2 nautical miles offshore (Phu Yen province) (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 15 A *thúng xoài* or *xoài máy* bamboo boat fitted with sternpost, rudder attached with pintle and gudgeon, a stem, and a decorated *ngà* (cathead). The engine is located under the wooden deck. The hull is reinforced by wooden thwarts, futtocks, floor timbers, and stringers (Binh Thuan province) (© C. Pham 2013–2014)

Basket boats are not just round. They can also be boat shaped, used in the form of small fishing canoes (c. 4 m in length) in inland waterways and harbors, or can be long and narrow (12–15 m) racing canoes used during water festivals (with 20–28 rowers).

The most amazing form of basket boat is the double-ended boat-shaped surf boats well adapted to the surf along the exposed beaches in the provinces of Thanh Hoa, Quang Tri, Thua

Thien-Hue, Binh Dinh, and Phu Yen where they can still be seen gracefully braving the waves. These beautiful basket boats are between 6 and 8.5 m long and 1.3–2.6 m wide and operated by a crew of three to six fishermen (Fig. 16).

The hull is reinforced by topside planks and by an inner structure composed of floor timbers and futtocks. Now, the large boats are all powered with a diesel engine (and a large steering-scuttling oar aft when nearing the

beach). They go fishing for the day (Hue) or overnight (Phu Yen), between 15 and 25 nautical miles offshore (Fig. 17). During the turmoil of the “boat people” refugee exodus in the early 1980s, some small 5–7 m versions of these basket boats and even smaller ones sailed as far as Hong Kong.

In the past, large sailing basket boats were operated by sail and oar. American Captain John White, on a mission in 1819, noted, “*They possess a great degree of stability, bearing a great press*

of sail, and are most excellent sea boats; they carry from one to three, very well cut, and neatly made lateen sails” (White, 1824, p. 57).

These bamboo-hull sailing vessels could reach 20 m long. They were used traditionally for transporting products such as rice, *nước mắm* (a condiment fish sauce), salt, dried fish, basket-work, or ceramics along the coast between the provinces of central and southern Vietnam. The large ones could also travel to Cambodia and Siam, said to carry as much as 8,000 jars of

Boats in Vietnam,

Fig. 18 Coaster of the Tonkin Gulf entering [the harbor of] Tourane [Da Nang]. “We saw in Tourane a coaster from the Tonkin Gulf, remarkable with its curved sail. . . the sail is solid but heavy, and tacks really well. . . Aft, . . . a rudder with pintle and gudgeon. . . These boats are never painted, . . . they have floor timbers, frames, planking, the maximum width is aft of amidships and they are about 18 m in length and 4 m in width” (Pâris, 1843, pp. 50–51, plate 48)

nước mắm, equivalent to about 120 t (Pietri, 1943, pp. 51, 61) and bringing back rice.

They were commonly called *ghe nang*, *ghe giã*, and *ghe câu* if they went fishing or *ghe bâu* when trading, but these names are generic, since the latter denomination also refers to fully wooden planked coasters.

These large traders have now disappeared, and the small fleets remaining in Thanh Hoa, Quang Tri, Thua Thien-Hue, and Phu Yen are the only descendants of this unique tradition.

Planked Boats from the Southern Border of China to Quang Binh Province

In terms of planked hulls, the boat tradition of the north of Vietnam can clearly be distinguished from the traditions of the center and the south of Vietnam. In the north the boats were constructed with features that can be associated with Chinese boatbuilding, such as battened sails, a high poop, a large beam aft of midships, planking edge-fastened with iron spikes, and bulkheads. Boats nowadays have retained some of these traditional features, but the working fleet is becoming replaced by the same blue and red modern-style vessels, found in hundreds in the ports of Hai Phong or Quang Ninh.

However, the surviving traditional wooden working boats in the Gulf of Tonkin are still

constructed with a flat bottom based on a plank keel that rises fore and aft. The planks are still edge-fastened with iron nails, driven in skewed distinctive triangular recesses. The floor timbers and futtocks that form the frames are bolted to the planking. The hull is partitioned into holds by bulkheads which are structural rather than watertight divisions. As in the Chinese tradition, the greatest beam is aft of amidships. The hull shape clearly shows a bow that is low on water and a high stern that hangs over the water. The boats from northern Vietnam do not have *oculi* or any other particular decoration. During the age of sail, their distinction lay in the Chinese reddish brown battened sails, tanned with *củ nâu* (*Dioscorea cirrhosa* Lour.) and still nowadays seen on the tourist junks, largely for ornamentation (Fig. 18).

The sailing vessels that used to do coastal trading and long journeys down to Siam and up to China were called *ghe mảnh* (and correspond to the *ghe bâu* of central and southern Vietnam described later). They reached 15–25 m in length, 4–5 m in beam, and transported 35–60 t. Fishing junks or river barges were also constructed according to the “northern” tradition.

In the mid-seventeenth century, the navy of the Trinh Lords in northern Vietnam counted over 400 galleys. The war galleys in Tonkin and Cochinchina were long, propelled by about

Boats in Vietnam, Fig. 19 A Cochinchinese galley with ten pair of oars, belonging to the governor of the district of Turon (Staunton, 1797, p. 341, engraving IV). Sir George Staunton, secretary of Ambassador Macartney in 1793, described: “A person of some rank soon arrived at Turon. . . He came in a large decked galley, of a light and sharp construction, formed for quick sailing. The rowers, who were very numerous, rowed in an erect posture, and pushed the oars from them, making short and frequent

strokes. A state cabin was erected, on the middle of the deck, painted in lively colours; each end of the galley was decorated with streamers of different colours and figures. The state cabin was, on the outside, surrounded with spears, and various ensigns of authority. The principal officer, who came in her, was dressed in loose robes of silk, had the polished manners of cultivated society, and was attended by a Chinese interpreter” (Staunton, 1797, p. 331)

40 rowers. The hulls were nicely lacquered or painted, with skillfully carved gilded prows. They sometimes had one mast and were fitted with guns for war. They were often described by travelers who visited the court and witnessed royal pageants (Fig. 19). The navy in Tonkin did not develop much during the subsequent years, but the sailing junks survived until the early 1990s. Now they can only be seen on romantic postcards.

Planked Boats from Quang Nam to Binh Thuan Province

The traditional double-enders in the center and south of Vietnam (Fig. 20) are the true and sole survivors of the past, the remainders of the beautiful sailing vessels of Vietnam praised by foreigners (Paris, 1843; Paris, 1942; Pietri, 1943; Poujade, 1940; Staunton, 1797; White, 1824).

The hull is pointed at both ends. The planks join in the stem and sternpost which both rise high above the water. It has no keel and is constructed plank first. A central plank is laid and joined in the stem and sternpost (Fig. 21). Then the strakes are fitted, dowelled edge to edge. Only when the plank shell has been constructed are the frames fitted. The fastening of planks was until recently done with treenails only, no iron nails used to enter boat construction in the center and south of Vietnam. This is a trait in common with Southeast Asian shipbuilding which differs greatly with the tradition of northern Vietnam and China. Now the planks are still mostly dowelled but a few iron nails are sometimes used for repairs.

These boats do not go far offshore and tend to fish on a daily basis near the shore. Their length varies between 8 and 15 m, and they are usually

Boats in Vietnam, Fig. 20 Traditional double-end. This is one of a very few surviving samples of a traditional boat with a sail, used in the sheltered bay of Xuan Dai (Phu Yen province) (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 21 Traditional shell-first construction (Quang Nam province) (© C. Pham 2013–2014)

operated by a crew of three or four fishermen. Smaller ones can be operated by two people.

The traditional boats, past and present, are decorated with *oculi* on the bow. The *oculi* in the center of Vietnam are long and lanceolate, painted on the sides, distant from the stem or median plank. The painting of the eyes is an important ceremony in the boat construction process. The hulls are usually not painted but protected by layers of *dầu rái* and decorated

with bright-colored wales. Another specific feature of the traditional boats is the *ngà* or *ngà gác neo* (cathead) from which the anchor is dropped and over which the anchor cable rides, but it is also used as the onboard altar and incense burning spot and to repulse the evil spirits. In certain parts of Vietnam, such as the province of Khanh Hoa, the *ngà* is still decorated, carved, and painted, but in many cases, only a simple timber remains (Figs. 22 and 23).

Boats in Vietnam, Fig. 22 Traditional double-ender, with *oculi*, *ngà*, and a gracefully curved and carved retractable rudder that hangs on the sternpost with long iron gudgeons (Phu Yen province) (© C. Pham 2013–2014)

The traditional double-enders in the province of Quang Nam retain another element reminiscent of the age of sail: the bow board or daggerboard that slides in a slot in the stem. This arrangement, like the rudder fitted in a slot in the sternpost, was probably adopted because a daggerboard fitted through the basketry bottom of a traditional boat was problematic. Daggerboards reduce the tendency of a vessel to drift sideways – to make leeway – and thus improve the ability to sail into the wind. It was adapted to wooden hulls too, and although all traditional double-enders are nowadays powered by engine, some still have and use a bow board (Fig. 24).

Described since the eighteenth century, the larger coasters of central and southern Vietnam which conducted long trading journeys as far as China, Siam, and Singapore were called *ghe bâu*. In the records, the “*gai bao [sic] is without contradiction, the most curious type, the most original and also most attractive of the boats of the coast of Annam, and which better characterizes the local construction*” (Audemard, 1971, p. 17) (Fig. 25). Some had a basket hull (Quang Nam, Quang Ngai), and some were completely made of wood (Phu Yen, Phu Quoc island). When fitted for fishing, they were called *ghe câu* and were

similarly built with just a few differences on the upper structure. The large coasters were built and used (and adapted with engine) until the 1980s. The very large sailing *ghe bâu* that could load 300 t of cargo, such as those of Mui Ne described in nineteenth-century records, were long gone by the 1940s (Pietri, 1943, p. 51). The *ghe bâu* could be recognized by a rounded hull that was large amidships but with incurving topside strakes midships (tumble home), said to minimize the harbor dues that were calculated on the beam measured amidships (Ky, 1875, p. 223). In the 19th century, usually of a length between 20 and 30 m, with a tonnage of 60–120 t, hundreds of these boats used to compose the fishing and trading fleets of most of the main harbors in the center and in the south of Vietnam, laden with either fish, salt, *nước mắm*, or rice (Fig. 26). The *ghe cửa* were of similar build but were smaller and operated near the river mouths. Between 1778 and 1819, the Vietnamese court chronicles account for the construction of 235 *ghe bâu* as part of the imperial fleet (Li, 2004, p. 121). The navy of the Nguyen Lords in central Vietnam dramatically developed between the early seventeenth century and the beginning of the nineteenth century. The numbers increased from

Boats in Vietnam, Fig. 23 In southern ports of Phan Rang, Phan Ri, or Phan Thiet, the double-enders are bulkier and have a wider beam and no chine at the turn of the bilge. Their bow and stern rise high but are not as raked as those of the traditional boats from central Vietnam. A less

elegant and simpler square blade that slides in a slot in the sternpost is raised while the boat is anchored. A short carved and painted *ngà* stands abaft the stemhead (Binh Thuan province) (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 24 Traditional double-ender, with bow board, auxiliary sail, and elongated *oculi*. In general, hull shapes in Quang Nam and Quang Ngai appear more slender than in the southern provinces of Khanh Hoa or Binh Thuan (Quang Nam province) (© C. Pham 2013–2014)

100 to 150 war galleys for the first Nguyen Lords in the early seventeenth century to a fleet composed of over 1,500 ships for the first Nguyen emperor *Gia Long*.

Stitched Boats

In the lagoon near the ancient imperial city of Hue survives the unique descendant of another construction technique in which the planks were stitched together. In the early 2000s, and much more in the 1980s, the planks were still stitched,

albeit with modern materials such as nylon rope and small piping. Now, only the shape remains since this kind of boat is constructed of riveted aluminum sheets (Fig. 27).

These *ghe nôl* or *ghe nôc* (called as such when they were stitched) or *ghe ðò* (nowadays) were house boats used in the rivers, canals, and lagoons. Made of five long planks, the hulls had a very narrow beam (1.5–2.5 m) with a double chine and reached 15–17 m in length. The bow and stern were particularly

Boats in Vietnam,

Fig. 25 For Commander Louis Theophile Audemard who sailed in Vietnam in the early twentieth century, “amongst the myriad of junks that sail in the China seas, the gai bao [sic] is unique” (Audemard, 1971, p. 16, plate 5, p. 17)

大
果
船

B

recognizable, the planks reaching quite high above the water and terminating in a flat transom. In the past, they were propelled by cotton sails with battens in the Chinese style, but they have been powered by an inboard engine since the 1980s (Fig. 28).

Based on several historical descriptions, it appears that the planks of the *ghe nôc* were stitched together by individual stitches and not sewn (which implies a continuous thread such as in Indian boats). The stitches were not attached to lugs either as seen in archeological material in

Boats in Vietnam, Fig. 27 The hull of the *ghe dô* has retained the shape of the stitched boat, *ghe nôm*, but is made out of tin or aluminum sheets and is powered with an engine. These houseboats still host entire families who

live in the numerous arms of the Perfume River and in the lagoon of Hue. People still remember them being powered by sail (© C. Pham 2013–2014)

Boats in Vietnam, Fig. 28 *Ghe nôm* drawn by Jean-Baptiste Pietri, inspector for the Directorate of Fisheries in Saigon in the 1940s (Pietri, 1943, plate LI)

Southeast Asia (in the lashed lugs tradition, protruding lugs are left out in the carved planking. The planks are then edge-dowelled and their frames, thwarts, or ribs are lashed down to the lugs). The stitched boats in Vietnam seemed to have been constructed in a different fashion, although as in the lash-lug construction, the fastening was not visible from the outside.

Different techniques are described across time for the stitching of the planks, yet the main principle remains similar. Holes were drilled in the

planks through which threads were inserted to stitch the planks together. The seam was then protected by a wadding of tree bark which was compressed under bamboo laths. The bamboo laths overlapped like tiles, and flat wedges were inserted between them and the stitches in order to tighten the stitching and thus compress the wadding under the stitching (Fig. 29). Any gaps in the seams were then paid with a mix of *tram* tree and coal tar (Pietri, 1943, p. 72) and required constant maintenance.

Boats in Vietnam, Fig. 29 Stitching system of the *ghe nớc* (After Amos, 1998, p. 89)

Boats in Vietnam,
Fig. 30 Mekong freighter
(© C. Pham 2013–2014)

There are many mentions of other larger types of stitched boats in the historical record, from the mid-seventeenth century up to the late nineteenth century (Cadière, 1921). These boats were described as seagoing sailing vessels that could travel from the center of Vietnam as far as Siam or China. Samuel Baron in 1630–1640 wrote that he traveled from Tonkin to Siam aboard this kind of boat in 23 days (Baron, 1808, p. 665). “They have about five hundred other boats called *twinqaes* [sic], which are good and swift to sail, but too weak for war, being only sewn together with rattans; however they serve well enough for transportation of provisions and soldiers. In one of these boats I was forced to go to Siam the last year . . . thanks be to God, we got our passage in twenty-three days to the admiration of all that knew of it.”

The stitched sailing boats seem to have disappeared in the late nineteenth century and,

in the 1940s, were only recorded as small riverine fishing house boats, the *ghe nớc*.

Planked Boats from the Mekong Region

A great traffic of freighters animates the numerous large canals and arms of the rivers in the Mekong Delta. There, the boats are very rounded and run low in the water, with just a few centimeters of freeboard (Fig. 30).

They transport paddy, sand, gravel, bricks, wood, coal, and sugar cane in open holds or have closed holds to transport bagged goods (such as cement, fertilizer, flour, and polished rice) or are live fish carriers with free-flooding fish wells.

The tradition in the southern region seems to blend north and central construction techniques. The boats are double ended, constructed shell first with full-length planks, and the strakes are fastened edge to edge with iron nails.

Boats in Vietnam,
Fig. 31 “Flat red nose” or
ghe chài (© C. Pham
 2013–2014)

Interestingly, they have no stem or sternpost per se, and the planks join at both ends, tapered in the stern and bow so that the hull looks like a mandolin's body. Floor timbers are inserted after the planking is complete. Futtocks support the top-side planking. Transverse partitions or bulkheads reinforce the structure. The beam is wide, ranging from 1/4 to 1/3 of the length of the cargo freighter. These river crafts vary greatly in size, between 15 and 25 m.

Among the variety of boats in the Mekong, there are two main kinds that are easily recognizable, thanks to their particular bows. As the planks run to the bow, they terminate either in a flat horizontal timber that looks like a “flat red nose” as described by the locals (boat called *ghe chài*) or they end on a stem that rises high and looks like an “elongated blue nose” (boat called *ghe cà vom*) (Bogani, 2001, p. 287) (Figs. 31 and 32).

The *oculi* on the bows in the south of Vietnam are rounder than in the center of Vietnam and usually painted very far forward; some are very large in a teardrop shape or very small and round like marbles. For steering, the Mekong riverboats all have centerline rudders that are attached with pintle and gudgeon and are easily retracted, because of the numerous sandbanks and uneven depths of the Mekong, which vary greatly with the tides. In the past, sailing boats with triangular sails made of palm leaves carried on three masts could reach Saigon [Ho Chi Minh City] and the

Boats in Vietnam, Fig. 32 “Elongated blue nose” or
ghe cà vom (© C. Pham 2013–2014)

neighboring ports deep inland to load or unload their cargo. The combination of long oars and of the power of the tide assisted them in sailing up and down the rivers. Chinese junks also operated in the channels of the Mekong due to the long history of the Chinese who settled there since the seventeenth century (Audemard, 1971; Bogani, 2001; Poujade, 1946b). These boats have disappeared in recent years.

Bamboo Sailing Rafts

“Rafts are found everywhere, but rafts worthy of the sailing vessel title are almost impossible to find” (Paris, 1939, p. 14). In Vietnam, however, there used to be sailing rafts fitted with sails and

B

Boats in Vietnam, Fig. 33 Sailing bamboo raft with centerboard and small engine (Thanh Hoa province) (© C. Pham 2009)

daggerboards. They were common in the north, in the provinces from Nam Dinh down to Quang Tri, and are still in use in the area of Thanh Hoa. Fitted with engines, they do not use their sails anymore, but in the mid-1990s, fleets of them could still be seen going about 30 miles offshore (Fig. 33).

The characteristics of the sailing rafts varied according to the region, most specifically in the number of bamboo poles, the mast steps, and the daggerboards. The raft could be composed of 8–24 bamboo poles, to which larger poles were lashed on the sides to form a strengthening framework. Sometimes, they could also be secured to a wooden crossbeam setup on the fore-end of the deck, which piled the poles up vertically, creating as such some sort of pseudo-washboards. They could reach 9–10.5 m in length and 1.6–2.3 m in width, depending on the number of bamboo poles used (Belcher, 2004; Burningham, 1994; Claeys, 1942; Pietri, 1943). Now, the bamboo poles, set in parallel, are braced and lashed together with fence wire or nylon, but in the past, they were fastened with bamboo strips, rattan, or husk.

If in the 1990s sailing fleets could still be seen across the horizon, by the year 2000, they were motored but still using their boomed lugsails once offshore (Belcher, 2004). Styrofoam blocks have been used increasingly since the 1990s to provide the primary buoyancy, and the bamboo is only used for the structure. In the modern bamboo

rafts, the Styrofoam blocks are covered above and below by narrow strips of split bamboo for protection and “quilted” together with the same heavy nylon fishing line that is now universally used to lash the bamboo structure together.

Conclusion

The variety of boats seen nowadays is decreasing dramatically. Some boat types described in the 1940s and in the 1960s are long gone, and surviving traditions will not be renewed. New fishing practices, new regulations, new materials, modern technology, and safer navigation contribute to new seafaring conditions and therefore to the birth of a new fleet.

Yet there is still a lot to learn from boatbuilders today and from the boats that survive from the past. Because a boat is not only the product of function and of environment, a boat also reflects the mind of the boatbuilder and the culture, the socioeconomic contexts, and the history it belongs to. The diversity of boats can reflect changes, adaptations, and cultural affinities across time. For example, it is possible to understand the differences in hull construction as related to the two main cultural spheres that shaped Vietnam’s history: that of the Dai Viet and that of Campa. North Vietnam was under Chinese domination for over 1,000 years and

Boats in Vietnam,

Fig. 34 Fishermen repairing their nets on the beach of Mui Ne (Binh Thuan Province)
(© C. Pham 2013–2014)

the boatbuilding traditions of the Dai Viet included Chinese features. Central and southern Vietnam were Cam lands, and boatbuilding in these regions, albeit progressively controlled by the Nguyen Lords since the sixteenth century, includes features that can be related to other boat traditions in Southeast Asia. This very simplistic explanation shows how a parallel can be made between technology and history. Yet, the intensive waves of migration that occurred in the country since the tenth century up to the latest upheavals of the twentieth century also mean that traditions and craft have been displaced along with people. Some northern-style boats can be found in the south of Vietnam; Chinese boats were constructed in the Mekong region (Poujade, 1946a); the *ghe câu* of Quang Khe (north) was similar to the *ghe câu* of Binh Thuan (south), with the same rudder and even identical *ngà* decoration (Pietri, 1943, p. 80), and bamboo-basket hulls are found everywhere along the coast.

Unfortunately, the poor archeological record does not yet contribute much to the discussion of the origins and the continuity of the different boat types in Vietnam. However, sailing boats, royal galleys, war vessels, and even small fishing junks attracted the eye of foreign travelers who

mentioned them in their journey's accounts or official reports. So other research approaches, such as ethnography and history, participate in this discussion and can help to constitute a wide and detailed record of boat use and construction since at least the seventeenth century. Multiple factors contribute to the design and shape of a boat, some more obvious than others. To discuss with boatbuilders and fishermen today about seafaring, boat use and boat construction can help us to understand elements that are not always related to function and not readable in the archeological or iconographic record. Providing a historical context to these boat types also illustrates a continuity of use and adaptation that can help to understand technological changes. Seafaring, fishing, bird nest collecting, shipwreck salvage, and goods transportation were common to the daily life of the coastal people of Vietnam living at the heart of the great maritime trade routes in Southeast Asia.

In summary, this introduction outlines the main families of boats that could be related to different maritime activities and engagements that occurred across time along the coast of Vietnam. So in a country often described as a long shoulder pole with a rice basket at each end (Mekong and Red River Deltas) and inhabited

by rice farmers and water buffaloes, the study of the boats of Vietnam can provide a complementary perspective to the people along the coast whose life was also shaped by their maritime environment (Fig. 34).

Boats of the Precolonial Philippines: Butuan Boats

Ligaya Lacsina

Department of Archaeology, Flinders University,
Bedford Park, SA, Australia
Archaeology Division of the National Museum,
Manila, Philippines

The Butuan Boats (also known as *balanghai*/*balangay*) refer to the incomplete remains of planked boats excavated from about 2 m of waterlogged alluvial sediments in Barangay Libertad, Butuan City, Philippines (Fig. 1). Reports say that the remains of between 9 and 11 boats have been discovered by looters along what are believed to be the shores of a former river, all within a 1 km radius (Cembrano, 1998; Clark et al., 1993; Ronquillo, 1997; Salcedo, 1998). However, archaeological researchers have only confirmed six sites to date.

The first Butuan Boat was partially unearthed in 1976 by looters searching for buried coffins containing valuable grave goods including Chinese ceramics and gold ornaments. Using long metal rods to probe through the earth for the wooden coffins, they accidentally came upon the timbers of Boat 1. The find was reported to local government officials, who in turn alerted the leadership of the National Museum of the Philippines. Personnel from the Museum's Archaeology Section investigated the boat's remains (Peralta, 1980a).

After several months, looters found the remains of Boats 2 and 3, just over 1 km south of the first boat. Excavations were undertaken on all three sites, though work on Boat 3, described as a smaller vessel, was not completed (Peralta, 1980a). Boats 1 and 2 were subsequently recovered and are displayed in exhibits managed and operated by the National Museum (Fig. 2).

Boat 5 was excavated in 1986 as part of a course on archaeological excavation and conservation organized by the Association of Southeast Asian Nations (ASEAN) and hosted by the

Boats of the Precolonial Philippines: Butuan Boats, Fig. 1 Map of the Philippines showing the location of Butuan City (Map: d-maps.com)

Philippines' National Museum (ASEAN 1986). It was located approximately one kilometer southwest of Boat 1 and less than 400 m northwest of Boats 2 and 3. It was also recovered and its planks are now stored in the Butuan City branch of the National Museum.

The excavation of Boats 4 and 9 commenced in 2012 and is still ongoing. The remains of these two boats were located slightly overlapping each other and just several meters east of the Boat 2 excavation trench.

None of the Butuan Boats were built with any metal fastenings, a characteristic of early South-east Asian plank boat construction that still persists in some areas today.

The most distinctive features of all but one of the excavated Butuan Boats are the rectangular lugs carved on the inner side of their planks. The lugs are drilled with holes to which frames and

Boats of the Precolonial Philippines: Butuan Boats, Fig. 2 Butuan Boat 1 at the Balangay Shrine, Butuan City (Photo: author)

thwarts could be secured with rope or cordage. Such boats are known as lashed-lug boats, used throughout the islands of Southeast Asia and beyond from well before the tenth century until the late nineteenth century. The oldest lashed-lug boat is the Pontian Boat found in Peninsular Malaysia dated to between the third and fifth centuries (Manguin, 1993). Lashed-lug boats were still observed to be in use in remote islands of Indonesia as late as the 1980s (Barnes, 1985).

The Butuan Boats are the oldest archaeological examples of watercraft in the Philippines. Early attempts to date the first three recovered boats in the 1970s and 1980s resulted in disparate radiocarbon ages dating to the fourth century, thirteenth century, and tenth century AD. Accelerator mass spectrometry (AMS) C-14 analysis was conducted in 2014 on seven timber samples collected from five boats,

including the three boats previously dated. The new calibrated results indicate the boat timbers date to between the late eighth and early tenth centuries AD (Lacsina and Van Duivenvoorde, 2014).

Boat 1

Boat 1 is exhibited at the Balangay Shrine in Butuan City which was erected several meters from where it was discovered.

The Boat 1 remains measure 10.2 m in length. It is composed of a keel plank, one strake on one side and two strakes on the other and several plank fragments. As it is displayed (Fig. 3), at least one of the strake fragments may not be in its original position, as its lugs appear to be slightly misaligned with lugs on adjacent strakes. One end of the keel plank is broken off. On the surviving end of the keel plank is a wing end (also referred to as a “wing stem” or “winged stem”) which was used instead of a stem or stern post. It is attached to the keel by dowels. The blade of a quarter rudder, reportedly recovered by looters, is also displayed at the shrine (Peralta, 1980b).

The timbers of Boat 1 were previously said to be of the species *Heritiera littoralis* (Peralta, 1980b). New identification was carried out in 2013 at the Forest Products Research and Development Institute (FPRDI) of the Department of Science and Technology (DOST) in the Philippines (Lacsina, 2013). The timbers of the keel plank, three plank fragments, and the wing end were identified as *Shorea* species. Another plank fragment was identified as *Vatica* species. The remaining plank fragment was identified as *Petersianthus quadrialatus*, as was the one dowel sampled. The quarter rudder was identified as *Eusideroxylon zwageri*.

An unspecified sample from Boat 1 was dated in the late 1970s at Gakushuin University in Japan to $1,630 \pm 110$ BP (GaK-7744) (Manguin, 1993; Peralta, 1980a). In 2014, two samples from the boat were subjected to accelerator mass spectrometry C-14 analysis at the Australian Nuclear Science and Technology

Boats of the Precolonial Philippines: Butuan Boats, Fig. 4 Drawing of Butuan Boat 2 as displayed at the Museum of the Filipino People, Manila (Drawing: A. Peñalosa and author)

Organisation (ANSTO). Sample OZQ841, taken from the keel plank, dated to $1,145 \pm 25$ BP or 904 cal AD. Sample OZQ842 from the wing end dated to $1,130 \pm 30$ BP or 924 cal AD.

Boat 2

Boat 2 is displayed at the Museum of the Filipino People in Manila. It is 11.3 m long. There are five strakes on one side of the keel plank, and two strakes on the other as displayed (Fig. 4). These were all identified by FPRDI as *Hopea* species. A wing end, identified as *Pterocarpus indicus* was recovered on one end of the boat, attached by dowels and mortise and tenon joins to what may be a fragment of the keel plank, identified as *Hopea*. A portion of a frame still secured to the keel plank and a strake at the time of excavation was not accessed at the time of recording and has yet to be identified. Though not formally identified, the rope used to secure the frame is believed to be from palm fibers (*Arenga pinnata*). As with Boat 1, the timbers of Boat 2 had previously been identified as *Heritiera littoralis* (Scott 1981).

An unspecified sample from the boat was originally dated to 700 ± 90 BP at Gakushuin University (Peralta 1980a). Additional two samples were dated at ANSTO in 2014. The keel plank (OZQ844) was dated to $1,200 \pm 30$ BP or 825 cal AD. The wing end (OZQ845) dated to $1,230 \pm 30$ BP or 787 cal AD.

Boat 4

The remains of Boat 4 include a keel plank, six strakes on one side, and three strakes on the other (Fig. 5). Roughly one half of this boat appears to be missing, with the surviving planks measuring 6–8 m long. As archaeologists have yet to expose either end of Boat 4, it is not clear if a wing end or posts were used on this vessel. FPRDI identified the keel plank and plank timbers as *Vatica* species. Another timber, found underneath Boat 4, atop Boat 9 and roughly perpendicular to both boats' planks, was identified as *Pometia pinnata*.

A keel plank sample taken from Boat 4 (OZQ846) was dated at ANSTO in 2014 to $1,150 \pm 35$ BP or 888 cal AD.

Boats of the Precolonial Philippines: Butuan Boats, Fig. 5 Preliminary excavation drawing of Butuan Boats 4 (left) and 9 (right) produced in 2013 (Courtesy of the National Museum; drawing: J. Santiago and A. Peñalosa)

Boat 5

The degraded and fragmented timbers of Boat 5 are currently stored in Butuan City. Based on the original excavation drawing, the boat is about 11.5 m long. It is composed of a keel plank and seven strakes on one side, eight strakes on the other. Seven frames were also recovered, as was a wing end made up of two segments. The keel strake and ten sampled plank fragments were all identified as *Pistacia chinensis* by FPRDI, confirming earlier findings (Abinon, 1989). Three of the frames were identified as *Vitex parviflora*, while the remaining four frames were identified as *Dimocarpus* species. One dowel was also identified as *Dimocarpus*. Both segments of the wing end were identified as *Pterocarpus indicus*.

In 1988, an unspecified sample from Boat 5 was dated at the Australian National University (ANU) Radiocarbon Dating Laboratory to 960 ± 70 BP (ANU 6193) (Abinon, 1989; Fallon, 2013; Ronquillo, 1997). The keel plank was dated at ANSTO in 2014 to $1,150 \pm 30$ BP or 890 cal AD (OZQ848).

Boat 9

While the archaeologists have not completed the excavation of Boat 9, it appears to be at least

twice the size of any of the other Butuan Boats (Fig. 5). Its timbers are also relatively more degraded than those of the other boats. It is composed of a keel plank, a wing end, and a still undetermined number of strakes, which appear to not have any lugs at all.

As of this writing, only two samples have been collected from Boat 9 for wood species identification at FPRDI. The keel plank was identified as *Vatica* species. The wing end could not be identified due to its advanced level of deterioration.

The wing end sample collected from Boat 9 dated to $1,160 \pm 30$ BP or 879 cal AD by ANSTO in 2014 (OZQ851).

Construction

Metal fastenings were not used in the construction of any of the Butuan Boats. Their builders edge joined the planks with wooden dowels. The edges of the keel plank and all other planks were drilled with holes through which dowels were inserted to fit tightly. In the cases of Boats 1 and 5, a number of dowels were further locked into place with wooden pins inserted through the planks and into the dowels (Fig. 6).

With one exception, all of the examined boats are lashed-lug boats. A series of protruding rectangular lugs were carved from the inside of each

Boats of the Precolonial Philippines: Butuan Boats,
Fig. 6 Example of plank fastenings based on Butuan Boat 1. Some of the dowels of Boats 1 and 5 were locked

in place with wooden pins inserted through the planks. No such locking mechanism has been observed in other Butuan Boats (Drawing: author)

plank; with the planks assembled, all the lugs are aligned crosswise. Frames and thwarts could then be secured by rope or cordage to the holes drilled through the lugs, adding strength through compression to the boat structure.

Dowelling and lashed lugs are generally considered to be distinctive characteristics of a Southeast Asian boatbuilding tradition. None of the Butuan Boats possess a true keel to cut through water; they were instead designed with a keel plank. The fore and aft ends of any of the Butuan Boats have not been determined.

Lugs and Lashing Holes

Each of the Butuan Boat keel planks is different, particularly in regard to arrangement of the lugs (Fig. 7).

The builders of Boat 1 carved the lugs on the keel plank in sets of three, except for the first two, which are single lugs, and the third, which is a paired set. All but the first lug, which is not drilled, have three pairs of lashing holes. The holes are drilled from either side of the outer lug to the top.

The lugs on the keel plank of Boat 2 were all carved in pairs and drilled with two pairs of lashing holes. As with Boat 1, the lashing holes were drilled diagonally from the outer side of the lugs to the top.

Boat 4's keel plank was carved with single lugs, as well as a continuous raised ridge that runs the length of the keel and through the center of each of the lugs. Two pairs of lashing holes

were drilled through diagonally from either side to the top of each lug.

The keel of Boat 5 stands out from the other keel planks quite distinctly. Instead of lugs, it has a continuous raised ridge, wider than the ridge on Boat 4. The lashing holes are drilled through the ridge, from side to side.

All other planks of each of the Butuan Boats have single lugs which were drilled with the same number and in the same fashion as their respective keel planks' lugs. The lugs on the planks of Boat 1 have three pairs of lashing holes, while Boats 2 and 4 have two pairs of lashing holes all drilled diagonally from side to top. In contrast, the lugs on the planks of Boat 5 have two lashing holes drilled straight through from either side. The design of the lashing holes would affect the manner in which rope and cordage could be secured.

Lug Spacing

A pattern of lug arrangement is evident in the surviving lashed-lug Butuan Boats. Lugs are more or less evenly spaced from either end except for a noticeable gap with an absence of lugs around the widest part of the boat. One end of the boat is invariably longer and more pointed and has more lugs than the other shorter, more rounded end.

Wing End

Only one end of only Boats 1, 2, and 5 survived. Neither end of Boat 4 has yet been uncovered,

Boats of the Precolonial Philippines: Butuan Boats, Fig. 7 Lugs and lashing holes on keel planks of Butuan Boats 1, 2, 4, and 5 (Drawing: author)

while only one end of Boat 9 has been exposed as of this writing. All the surviving ends of the boats show a wing end, rather than a stem or stern post. It is not clear if the opposite ends of the boats were likewise designed to use a wing end.

Acknowledgments The author would like to thank AINSE Ltd for providing financial assistance (Award No. 13504) to enable the AMS C-14 analysis of Butuan Boat samples. Thanks also to ANSTO, FPRDI, Flinders University, and the National Museum of the Philippines for supporting the author's research.

Bone Technology in Africa

Alice M. Choyke

Particular cellular structures in the hard tissues of animals provide potential raw materials for manufacturing tools and ornaments. Mammalian bones and teeth provide the bulk of the raw material not only because of their form but also because they were available in the refuse derived from the consumption of meat. Egg and mollusk shell (gastropods and bivalves) were also modified. It is possible that, like ivory in later periods, they might have been sought after for the sake of the shell raw material itself. In parallel, since osseous tissues come from living animals which often had important symbolic significance to the humans exploiting them, their bones may also have had a variety of special significances in traditional tool manufacture. At the beginning, bones were used rather than modified in regular ways, but quite early on humans used a variety of techniques (cutting, scraping, abrasion, and drilling) to produce standardized objects. Until the Late Bronze Age in the second millennium BC, flaked stone tools, rough stone surfaces, and polishing materials were used to manufacture quite sophisticated objects.

As it was the cradle of humankind, it is not surprising that Africa was the scene of the earliest bone working in the world and some of the latest as well, representing almost 2 million years of transforming the hard tissues of animals into tools and ornaments. Furthermore, African bone technology is also distinguished by the use of two special raw materials: ivory and ostrich eggshell. As elsewhere, however, animal bone lay at the

heart of technological processes while antler, a staple material in Europe, was unknown. Shells, riverine or marine, were used as ornaments almost everywhere across the continent and from remarkably early times in the Middle Stone Age to the present.

Outside Africa, until quite recently, the earliest, securely dated worked bones, small split-based projectile points, came from the Central European Szeleta culture at around 35,000 BP, representing the earliest securely dated manufactured objects in Europe, coeval apparently with the arrival of anatomically modern humans in Europe. Worked wooden artifacts from the sites of Clacton and Lehringen as well as three wooden spears found at the 400,000-year old site of Schoeningen in Germany, however, show that Middle Pleistocene European hominids used wood. *Homo erectus* craftspeople could scrape and shave wood so handily that working bone should have presented few problems. There are also examples from this early time period in Europe of large mammalian phalanges, deer antler and diaphysis shaft fragments being used as retouchers for making stone tools. There is even one example from Italy of bifacial tools flaked from an elephant long bone (d'Errico & Backwell, 2001; d'Errico, 2003).

Some of the chronological and spatial gaps in the distribution of these early bone objects from Europe and Africa revolve around the survival of bone on archaeological sites. Very ancient sites are rare everywhere in the world. Furthermore, and importantly, preservation of organic, osseous materials was dependent on the way those objects were used, where they were discarded, and the natural conditions prevailing in those places. Acidic soils destroy bone while root action and animal gnawing can also modify surfaces and shapes. Osseous materials of any kind, compared with stone, will begin to erode and break apart when exposed for more than a month or two in the open air. Thus, both cultural behavior with regard to tool use, location(s) of that use, and traditions of discarding worked bone after they broke compound natural conditions to affect what objects can be found by excavating archaeologists. Bone tools have not often been systematically

researched, perhaps because their study also requires such an intimate knowledge of the biology of the bones they derive from.

The Taphonomy of Worked Osseous Materials

What particularly makes any discussion of African bone tool technologies a challenge is the size of the continent, especially relative to the amount of published research which has gone on there. (Taphonomy is the study of the conditions and processes by which organisms become fossilized or are preserved.) This research has been quite localized in time and space. On the one hand, lands along the great Nile, from Nubia to Egypt have been intensively studied. However, the very grandeur of Egyptian civilization has meant that researchers have concentrated on the grand places, the palaces, temples, and burial monuments and emphasized ceramics and exquisite, special finds. Predynastic settlement has only recently begun to be investigated and even there the bone finds are rarely published in detail. Much less is known of the later prehistory and history of bone technology in the enormous territory of North Africa, best known archaeologically for the great Roman and Medieval Islamic cities whose ruins dot the shores of the continent.

On the other hand, because humankind is infinitely fascinated with its beginnings a great deal of attention has been paid to early hominid sites in South Africa, the Rift Valley and Congo. Over 50 years ago, Raymond Dart, the physical anthropologist famous for his discovery of the baby *Australopithecine* skull from Taung in South Africa (Dart, 1925), later interpreted some of the bone finds from the South African site of Makapansgat as being among the first “natural” tools used by these early hominid populations (Dart, 1949, 1962). Since then there has been debate concerning whether these artifacts were modified or simply used by these early hominids or were the result of nonhuman taphonomic processes such as erosion. However, such tools were never found, or rather they were not evident to the people working on these ancient sites and so the

idea was rejected. It was almost inevitable, given the relatively well-funded research on early human sites, regularly ongoing in Africa, that new finds would emerge to revive Dart’s ideas and even greatly expand them.

The First Humanly Modified Bones in the World—Termite Extraction Tools

Three of the most famous early hominid sites in the world, Swartkrans (Members 1–3, ca. 1.8–1.0 Mya) Sterkfontein (Member 5, 2.0–1.7 Mya), and Drimolen (2.0–1.5 Mya) are located in South Africa. These sites contain the first evidence for the systematic modification and use of long bone shaft fragments and horncores (the boney core within bovid horn sheaths) for tools (d’Errico & Backwell, 2001, 2003). These 68 tools were originally interpreted through microscopic analysis as tools for digging up tubers and working skins (Brain & Shipman, 1993). The bones from these three sites were later reexamined using a multidisciplinary approach that compared wear patterns on pseudobone tools created by known natural processes with the patterns on experimentally used bone tools and with the traces of wear found on the original objects (Backwell & d’Errico, 2005; d’Errico & Backwell).

It was immediately clear that the wear on the artifacts matched that neither on pseudotools nor on artifacts used for digging tubers or preparing hides. Wear traces on the working ends of tools used experimentally to excavate termite mounds most closely fit the wear traces found on these archaeological objects (Backwell & d’Errico, 2001). The bones used as raw material all show signs of weathering prior to use in that they have weathered breakage patterns as opposed to spiral fractures. In addition, compared to other bone fragments found at these sites the 68 modified bone objects stand out as a group since they are made from longer, broader bone fragments showing that they were intentionally selected by these early hominids. The researchers were able to find robust horncores with tips that had been reshaped by grinding.

The presence of such relatively sophisticated shaping suggests that even at this early date, modern human behavior was beginning to emerge, together with the ability to preplan objects according to culturally determined patterns. Although the technology used was far less complex than the completely shaped bone tools found at Middle Stone Age sites such as Blombos cave in southwestern South Africa or regularly encountered in materials from the Late Stone Age to the present day, there is still evidence that the location and direction of the facets produced on the tips represent planned behavior. The makers and users of these termite extraction tools, probably the robust australopithecine, *Paranthropus robustus*, seem to have had a clear understanding of the relationship between the shape of the tip and how the tools were going to be used (d'Errico, 2003; D'Errico et al., 2003). Such complex thinking was always previously associated with anatomically modern humans. The discovery and recognition of these tools have forced scientists dealing with human evolution to change their ideas about what defines modern human behavior.

The earliest specimens of anatomically modern *Homo sapiens* come conclusively from Africa at Omo Kibish in Ethiopia dating to 185,000 BP and Herto in Ethiopia dating to 165,000 BP. However, evidence for planned sophisticated tool making, especially complex techniques for modifying osseous materials for tools and ornaments or even symbolic expression, only appears, at the earliest, 50,000 years later. Students of the development of modern cognitive thought divide into two schools on this issue. One school, led by the scholar Richard Klein (2002), proposes a revolution in mental capabilities beginning around 40,000 years ago in Europe and some 5,000–10,000 years earlier in Africa. This can be seen for example, in the presence of ostrich shell disk beads at the site of Enkapune Ya Muto in Kenya dated to 45,000–50,000 BP. A smaller but growing group of researchers led by Brooks and Henshilwood have argued that technological complexity developed slowly in a piecemeal way along with what may be called modern human behavior (McBrearty & Brooks, 2000). Proofs of

this development may be found in the single-row barbed harpoons from Katanda in the Congo, which have been controversially dated to 90,000 BP (Brooks & Smith, 1987), and more securely in the well-dated finds from Blombos Cave dated to 77,000 BP.

Katanda and the Harpoon in Africa

Barbed harpoons have a special place in the history of bone technology of Africa (Yellen, 1998), demonstrating continuity in their basic form if not in their actual use. At Middle Stone Age Katanda, single-row barbed harpoons were found with remains of giant Nile carp. New dates seem to reconfirm that Katanda was a very early site (McBrearty & Brooks, 2000). The harpoons were dated using thermoluminescence techniques, and there is still debate whether the deposits where the harpoons and fish remains lay can be accurately dated using this method. It has also been suggested that the harpoons themselves may have been washed onto this terrace from later sites. The debate will probably only be resolved if more sites from this early date are found. The manufacturing technique used to produce the Katanda harpoons (D'Errico et al., 2003) was quite different from the technique worked out for the harpoons found at the Later Stone Age lakeshore site of Ishango in Zaire. Ishango is securely dated to around 25,000 BP (Brooks & Smith, 1987). The bone harpoons found there have been interpreted as signs of a fishing industry (Van Noten, 1982; Brooks & Smith).

It no longer seems quite so unreasonable that objects of such sophistication could have been produced so early in the history of modern *Homo sapiens*. Such single- and double-row barbed objects have also been found widely distributed across Africa on sites younger than 10,000 BP (for example, Camps, 1974; Camps-Fabrer, 1961; Haaland, 1992; Petit-Maire et al., 1983). Although the earliest harpoons from Katanda and Ishango in Central Africa are interpreted as having been used in fishing, there is ample ethnographic evidence showing that such barbed objects can also be used for hunting

land mammals, especially in bush land where the prey may not be visible. Mesolithic (Haaland) midden deposits at a lacustrine site from northern Mali dating to ca. 6900 BP contained 200 beautifully carved single- and double-row harpoons as well as fish hooks, long pins and a carved crocodile bone (Petit-Maire et al.).

Single-row harpoons were found at the Sudanese site of Esh Shaheinab in the Nile Valley as well as another late single-sided harpoon made from elephant ivory (Choyke, 1990) from the Middle Bronze Age site of Kerma (ca. 3500 BP), the capital of the Nubian Kingdom of Kush located on the Upper Nile in Sudan. Other, single-row barbed harpoons were discovered at two pre-Iron Age settlements (ca. 3000 BP) at Gajiganna on Lake Chad (Breurig, Neumann, & Van Neer, 1996). Later evidence, from a burial at the site of Daima I (around 2500 BP), also on the shore of Lake Chad, shows a double-row alternating barbed harpoon having been used as a weapon against humans (Connah, 1981). All these complex, fine objects were produced using a variety of techniques depending on the time period and local traditions. Whether used for fish, hunting land mammals or as weapons in human conflict all such objects required a disproportionate amount of time to produce, beyond what would have been practically necessary. Thus, their form has other social implications related to display and identity within and between groups of people.

Ornamentation and Symbolic Reasoning

The well-published Middle Stone Age cave shelter of Blombos overlooking the Indian Ocean is securely dated by thermoluminescence to ca. 77,000 BP. It is notable for the 40 standardized bone tools found there including the 3 finely crafted spearheads and 3 projectile points. These points were formed by scraping and then polished to give them “added value” possibly in exchanges designed to facilitate relationships between neighboring groups of people. Other bone points at the same site were used in leather working

(Henshilwood et al., 2003; d’Errico, 2003, p. 192). However, the site is also remarkable for a ruminant mandible fragment with 11 incisions grooved on it with a flint point (d’Errico et al., 2001). Together with pieces of ochre that were ground flat and incised with patterns this represents evidence of symbolic thinking.

Even more sophisticated symbolic thinking is evidenced by the much later incised long bone handle or rod dated to ca. 25,000 from Ishango Cave in Zaire. These repetitive regular groups of notches have been interpreted as representing some kind of mathematical thought (d’Errico, 2003) or as a record of regular events, perhaps associated with female cycles such as menstruation (Brooks & Smith, 1987). This question will probably never really be resolved.

Blombos cave excavations also revealed 19 tiny bivalve shells of *Nassarius kraussianus*, which had been artificially drilled, as evidenced by wear facets around the edges of the holes (d’Errico, 2005). Engraved ostrich shell found at the site of Diepkopf on South Africa’s Western Cape dates to 60,000 BP while ostrich shell beads dated to 70,000 BP came to light at Loiyangalani in Tanzania. Again, it has been argued that such sophisticated objects were designed not only for personal adornment but also for exchange, a social lubricant for acquiring social partners (Yellen & Brooks, 1995; d’Errico, 2003). Fish vertebrae drilled to be made into beads have been reported from Mesolithic sites in Central Sudan (Haaland, 1992).

Beads made of bone and mollusk and bivalves and, in particular, ostrich shell, continue to be made even today (Figs. 1 and 2) everywhere on the continent (Vialou & Vialou, 1981; Breurig et al., 1996; Camps, 1974; Camps-Fabrer, 1966; Connah, 1981; Choyke, 1990; Van Noten, 1982; Petit-Maire et al., 1983). Ostrich shell beads and engraved shells appear regularly on Neolithic sites across North Africa. Cowrie shells, often with their dorsal sides cut off so they lay flat on clothing or on the neck, were certainly used in North Africa by the Neolithic period. Since their form resembles the human vulva it is usually suggested that these shell beads are connected with fertility. In ancient Egypt, there are

Bone Technology in Africa, Fig. 1

Bone Technology in Africa, Fig. 2

depictions of women wearing cowrie shells. As in many other places around the world, they are often imitated in other raw materials like gold, bronze, and bone. All these kinds of bone and shell beads represent a technological tradition of fantastic antiquity which seems to grow sharply in complexity and become widespread about 6,000–7,000 years ago, in North Africa at least, with a variety of incised bones, decorative pins, and a variety of ornamental shapes produced in bone and shell. The Neolithic period in Africa also saw the advent of special tools and ornaments made from human teeth, long bones, and even crania—surely all with special, socially deeply embedded symbolic significance (Camps-Fabrer).

The Use of Ivory

Although drilled and suspended animals' teeth, and in particular canine teeth, are found around the world, the earliest use of ivory still seems to have been at Olduvai Gorge in Tanzania, as reported by Mary Leakey in the Olduvai volume. This material has not been studied as it is difficult to differentiate true and pseudotools made on teeth, but Mary Leakey described them as tools. However, with the extinction of mammoths, African elephant and hippopotamus ivory use became restricted to Africa and the Near East, certainly from the fifth millennium onwards, only reappearing in Celtic continental Europe at the end of the Iron Age and with the coming of the Romans.

In Africa, ivory was traded from Central Africa to the Nile Valley to make prestige goods and beautiful ornaments at least from the predynastic Middle Bronze Age (second millennium BCE). There is now evidence of this trade in the Iron Age from Botswana (Reid & Segobye, 2000). Ivory as a raw material was exported out from Europe through Egypt around the Mediterranean. Roman sites in provincial Europe frequently have objects made from ivory, manufactured elsewhere in the empire.

Manufacturing of ivory seems to have become common rather late compared to other raw materials. From the Kushite site of Kerma comes a

Bone Technology in Africa, Fig. 3

hippo ivory harpoon as well as elaborately carved inlays from elephant ivory (Choyke, 1990). Dynastic Egypt sees an explosion in the use of ivory as decoration for furniture and as beads, buttons, and statuettes, perhaps related to the widespread use of metal in bone and ivory industrial manufacturing. This tradition of ivory working continued into medieval times (for example in Ghana, Stahl & Stahl, 2004) and until recently in sub-Saharan Africa (Figs. 3 and 4).

Bone Tool Production in Later Prehistory

By the Neolithic period, bone working had developed into a multitude of variable industries using different combinations of techniques. Each group had their own standardized way of making tools and these were best made into pointed tools like awls and projectile points. Use was frequently made of ruminant metapodium bones, which can be grooved down the median line with a

Bone Technology in Africa, Fig. 4

pointed flaked stone tool and then easily split. Using one of the epiphyseal ends as a handle the diaphysis was sharpened through some combination of scraping with a flaked stone tool or abrasion with a rough-textured stone. This is an ancient technique, even preserved in a ritual form as a burial offering in the cemetery at Kerma where two new and identical mirror-image sheep metapodial awls from two different bones were deposited with the deceased (Choyke, 1990). Awls were used in leather-working and coiled basket working. Stone tools were the tools of choice in bone working until the end of the second millennium BCE in Egypt when metal tools took over. Stone tools, however, were still important at Kasteelberg, an Iron Age site in South Africa where a combination of hammering off the epiphyseal ends, grooving, splitting, and fine grinding and polishing were used to create beautiful bone projectile points or link-shafts for arrows. These objects have parallels with objects used until recently by San Bushmen (Smith & Poggenpoel, 1988). Simple bone awls based on

the spiral fracture of long bones were also common at Kasteelberg as elsewhere across Africa and the world. Otherwise, there are broad tendencies for bone to continue to be made into objects with beveled edges used as wedges, scrapers, and burnishers, especially for leather working and ceramic production.

It would be impossible here to go into all the different ways bone, ivory, ostrich-egg shell, and mollusk shell have been used in the last 6,000 years in Africa. There is a general tendency for bone objects to be made for increasingly special purposes. Often they were made to be parts of composite objects as fittings, handles, closures, and ornaments. Hopefully, as archaeological work continues in Africa it will be possible to present a more integrated picture of the way this ancient technology developed there.

Brahmagupta

R. C. Gupta

“Brahmagupta holds a remarkable place in the history of Eastern civilization” (Sachau, 1971). ► **Bhāskara II** described Brahmagupta as *Gaṇakacakra-cūdāmani*, jewel among the circle of mathematicians.

Brahmagupta was born in AD 598 according to his own statement: “... when 550 years of the Śaka era had elapsed, Brahmagupta, son of Jisṇu, at the age of 30, composed the *Brāhmasphuṭasiddhānta* for the pleasure of good mathematicians and astronomers.” Thus he was 30 years old in Śaka 550 or AD 628 when he wrote the

Brāhmasphuṭasiddhānta. That he was still active in old age is clear from the title epoch of AD 665 used in another of his works called *Khaṇḍa-khādyaka*. Prthūdaka Svāmin, an ancient commentator on Brahmagupta, calls him Bhillamālācārya, which shows that he came from Bhillamāla. This place has been identified with the modern village Bhinmal near Mount Abu close to the Rajasthan-Gujarat border.

We have no knowledge of Brahmagupta's teachers, or of his education, but we know he studied the five traditional *Siddhāntas* on Indian astronomy. His sources also included the works of Āryabhaṭa I, Lāṭadeva, Pradyumna, ► **Varāhamihira**, Siṃha, Śrīṣeṇa, Vijayanandin, and Viṣṇucandra. He was, however, quite critical of most of these authors.

The *Brāhmasphuṭasiddhānta* is Brahmagupta's most important work. It is a standard treatise on ancient Indian astronomy, containing 24 chapters and a total of 1,008 verses in *āryā* meter. The *Brāhmasphuṭasiddhānta* claimed to be an improvement over the ancient work of the *Brahmapakṣa*, which did not yield accurate results. Brahmagupta used a great deal of originality in his revision. He examined and criticized the views of his predecessors, especially ► **Āryabhaṭa I**, and devoted two chapters to mathematics. There have been many commentators on this work. The earliest known was Balabhadra (eighth century AD), but his commentary is not extant.

Chapter 7 is on *Gaṇita* (Mathematics). It deals with elementary arithmetic, algebra, and geometry. The subject is presented under 28 topics of logistics (arithmetical operations) and determinations, including problems related to mixtures, plane figures, shadows, series, piles, and excavations. He wrote in a concise and understandable style, whether dealing with simple mathematics or complex geometry. In the treatment of surds, Brahmagupta is remarkably modern in outlook. The *Brāhmasphuṭasiddhānta* includes formulas for the rationalization of the denominator, as well as a marvelous piece of pure mathematics in the rule for the extraction of the square root of a surd. Still more remarkable algebraic contributions are contained in a chapter entitled

Kuṭṭaka, which is a traditional name for indeterminate analysis of the first degree. The second order indeterminate equation

$$Nx^2 + c = y^2$$

is called *varga-prakṛti* (square nature). An important step towards the integral solutions of such equations is what is called Brahmagupta's Lemma in the history of mathematics. In modern symbology the Lemma is as follows:

If (α, β) is a solution of (1) with $c = k$, and (α', β') is its solution with $c = k'$, then $(\alpha\beta' \pm \alpha'\beta, \beta\beta' \pm N\alpha\alpha')$ will be its solution with $c = kk'$.

This lemma not only helps in finding any number of solutions from just one solution, but it also helps in solving the most popular case of $c = 1$, provided we know a solution for $c = -1$, or ± 2 or ± 4 .

In geometry, Brahmagupta's achievements were equally praiseworthy. He wrote a fine symmetric formula for the area of a cyclic quadrilateral, which appeared for the first time in the history of mathematics. Even more important are his expressions for the diagonals of a cyclic quadrilateral.

Brahmagupta's name has been immortalized by yet another achievement. A "Brahmaguptan quadrilateral" is a cyclic quadrilateral whose sides and diagonals are integral (or rational) and whose diagonals intersect orthogonally. He gave a simple rule for forming such figures in the *Brāhmasphuṭasiddhānta* (Chap. 7, verse 38): If a, b, c and α, β, γ are the sides (integral or rational) of two right-angled triangles (c and γ being hypotenuses), then $\alpha\gamma, b\gamma, c\alpha$, and $c\beta$ are the required sides of a Brahmaguptan quadrilateral.

Prior to Brahmagupta, the usual method for computing the functional value intermediary between tabulated values was that of linear interpolation, which was based on the rule of proportions. He was the first to give second order interpolation formulas for equal as well as unequal tabulated argumental intervals. Mathematically, his rule is equivalent to the modern

Newton-Stirling interpolation formula up to the second order.

The *Khaṇḍa-khādyaka* is a practical manual of Indian astronomy of the *Karaṇa* category. The author claims that it gives results useful in everyday life, birth, marriage, etc. quickly and simply, and is written for the benefit of students. The work consists of two parts called the *Pūrva* and the *Uttara*. The former comprises the first nine chapters and expounds the midnight system. The latter six chapters provide corrections and additions. This work has been studied by a great number of commentators, from Lalla in the eighth century to Āmarāja in the twelfth. It was translated into Arabic first by al-Fazārī (eighth century) and then by ► [al-Bīrūnī](#).

Brahmagupta's genius made use of mathematics (traditional as well as that which he developed) in providing better astronomical methods. He used the theory of quadratic equations to solve problems in astronomy. He knew the sine and cosine rule of trigonometry for both plane and spherical triangles. He supplied standard tables of sines and versed sines.

The historian of science George Sarton called him "one of the greatest scientists of his race and the greatest of his time."

Bread in Africa

Diane Lyons

Department of Anthropology and Archaeology,
University of Calgary, Calgary, AB, Canada

Bread and Bread-Baking Technologies in Africa

Bread is a dietary staple in North Africa, North-eastern Africa, and the Horn of Africa, and it is important in the diet of many Saharan and sub-Saharan people. African breads are made from the flours of a variety of cereals, tubers, and corms that are baked, steamed, and

sometimes fried to produce pancake, flat bread, leavened or slightly leavened loaves, or cakes using ovens, hearths, griddles, pots, and molds. Technical choice in bread baking is associated with the baking properties of bread ingredients and social group's culinary practices and preferences and does not represent evolutionary stages.

The Bread/Oven Porridge/Pot Bread/Griddle Traditions

Research of Africa's culinary practices includes the history of bread consumption and its associated technologies, an investigation that is far from exhaustive. Several researchers observe a general (but not absolute) culinary divide between bread-based cuisines that use ovens and griddles in North Africa, Northeastern Africa, and the Horn of Africa and porridge-based cuisines cooked in pots in many sub-Saharan societies. These scholars differ in their interpretations of the geographic extent of bread-consuming cultures and the number of associated technologies involved in Africa's culinary divisions. Problematic is the lack of clear definitions for bread and porridge. For instance, many types of African bread are made with a batter that involves boiling some of the fermented dough into thick porridge before baking the bread, especially when using non-gluten-containing ingredients (see below). This process causes the dough to become elastic and starches to gelatinize trapping gas that slightly leavens the bread as it bakes (Lyons & D'Andrea, 2003). Many African porridges are very stiff dough that is used like bread by diners who pull pieces of dough from the mass with their fingers to scoop up sauces served with the meal. Small viscous dough balls (*th'ollo*) are produced in northeastern high-land Ethiopia without boiling the flour in a pot. Instead soaked barley grains are roasted in a griddle and ground, and the flour is sieved and mixed with a liquid and formed into balls eaten with a spicy sauce (Lyons, 2007). Other porridge is gruel and eaten with a spoon or drunk from a bowl. Despite the lack of clear definitions, archaeologists generally apply the term porridge to any flour mixed with liquid and boiled in a pot

Bread in Africa, Fig. 1 Map of place names in the text (Source: Map by Diane Lyons)

regardless of the density of the final product. Bread is a dry food in the form of pancake or flat, molded, or slightly leavened loaves made in ovens, griddles, and pots. It is worth noting that the separation of Africa's starchy staples into bread and porridge traditions glosses over the complexity and variety of its cuisines.

In their interpretation of bread/oven porridge/pot cuisines, Edwards (1996, 2004), Haaland (2007, 2012), and Pope (2014) focus on traditions

in Ancient Egypt and Sudan (see Fig. 1). In Predynastic and Dynastic Egypt, bread was produced with flours of emmer wheat or hulled barley, both Near Eastern cereals that spread from the Levant presumably with the concept of bread baking. Haaland (2007, 2012, p. 330) suggests that the porridge/pot tradition developed in the Middle Nile with pottery and the collection/cultivation of wild sorghum in the early Holocene. It is widely believed that wild sorghum (and other

indigenous grass grains) was eaten for millennia in Northeastern Africa and the Sahara, but timing and location of sorghum domestication is still being determined (Haaland, 2007, 2012, p. 330; Neumann, 2005). Currently, sorghum domestication is firmly dated to 500 BCE in Nubia (Fuller, 2004), but earlier dates in the second millennium BCE are reported from Mahal Teglinos in the Kassala region (Baldados & Constantini, 2011). It is likely however that the porridge/pot tradition has multiple origins. Africa's earliest pottery is dated before 9400 cal BCE at Ounjougou, Mali, in West Africa as well as in the Nile Valley (Huysecom et al., 2009). Huysecom et al. suggest that pottery was developed in the West African Sahel with the reestablishment of grasslands in the early Holocene in order to boil grains of wild grasses rather than to bake bread.

Bread baking is also important in the Nubian region including domestic sorghum bread products baked on griddles (see below). Edwards (1996) suggests that the production of sourdough bread in the Middle Nile (e.g., Nubia) is unique for sub-Saharan African cuisines with the notable exception of *injera* in Ethiopia. In fact, *injera* is the staple pancake bread for the entire Horn of Africa (Ethiopia, Eritrea, Djibouti, and Somalia), a large geographic and culturally diverse zone. Depending on local crops, *injera* and many different types of fermented or unfermented flat or slightly leavened bread are made from flours of indigenous and Near Eastern ingredients baked on griddles. The widespread production of griddle baked bread in the Middle Nile and the Horn of Africa suggests that Africa has at least three culinary traditions based on distinct technologies: porridge/pot, bread/oven, and bread/griddle. Bread is eaten in the Sahara, North, East, southern, and West Africa, and in these societies bread is made of indigenous and nonindigenous grains, corms, and tubers that are baked in hearth ash, earth ovens, and griddles (see below).

Why different technologies? The choice to use griddles, ovens, or molds for bread baking is determined in part by the different performance characteristics of Near Eastern and African foods (Lyons, 2007; Lyons and D'Andrea 2003). Only Near Eastern cereals contain gluten, an elastic

protein formed when their flours are mixed with liquid to produce dough. If yeast is added and ferments, it produces carbon dioxide gas that becomes trapped in the dough's elastic structure causing it to rise. Sourdough leavening is common in Africa. It is produced with residue left in dough mixing containers or by adding dough saved from a previous batch. Barley and many varieties of wheat (e.g., emmer wheat and at least one wild ancestor of wheat) form gluten with poor leavening capacities. These cereal flours still produce viscous dough suitable for shaping by hand, a requirement for baking on oven floors and walls. Light airy bread was possible only after bread wheat, a variety with superior leavening capabilities, was developed in southwest Asia probably during the fourth millennium BCE.

African cereals (sorghum, millets, and *t'ef*) and other indigenous plants (*enset*) do not contain gluten, and their flours are made into fermented or unfermented batter or thick porridge and baked on griddles, trays, or in molds or shallow earth depressions. Only sorghum flours will form viscous dough suitable for baking in ovens, but it is nonelastic and will not rise. Lyons and D'Andrea (2003) suggest that griddle bread baking could be an indigenous technology that developed with the domestication (or use of wild varieties) of African foods. They hypothesize that because griddle technology can incorporate Near Eastern cereals as ingredients in pancake, flat and slightly leavened bread, and Near Eastern oven technology cannot bake bread from African foods with the exception of sorghum, then the domestication of African cereals may precede that of Near Eastern cereals in the Ethiopian highlands. Near Eastern cereals were then adapted to a preexisting African culinary practice. The timing of African cereal domestication (which does not preclude earlier use of wild varieties of these cereals) is gradually unfolding. The paleobotanical record for the first millennium BCE is dominated by Near Eastern cereals (emmer wheat and barley), but domesticated *t'ef* is also firmly dated to the fourth century BCE near Asmara in Eritrea (D'Andrea, Schmidt, & Curtis, 2008). During Aksumite times (third century BCE to 700 CE), crop diversity increased and included a mix of

indigenous and Near Eastern cereals (including sorghum, finger millet, and bread wheat) similar to cropping practices found in the region today (D'Andrea et al., 2008). However, the paleobotanical record may be biased by differential preservation of Near Eastern and indigenous cereals. For instance, different cooking practices favor charring and preservation of Near Eastern cereals but not indigenous ones (D'Andrea, 2008; Lyons & D'Andrea 2003).

Regional Bread History and Technology

Bread baking is ancient in Africa, but some baking practices leave little material evidence. 18,000 years ago wild tubers were made into a fine mush to feed young children in Kabbaniya, Egypt (Hillman, 1989). Pot boiling was unknown at this time, and plants may have been ground and then baked in shallow earth depressions similar to those used by the Tuareg (see below) (Close, 1995). Wild grass grains, including wild sorghum, were collected by nomadic hunter-gatherers-herders in the Sahara and along the Nile during the early and middle Holocene (Neumann, 2005). Foods may have been boiled in early pottery vessels, but ash bread is common with nomadic people and leaves no evidence. For instance, hunter-gatherers in southern Africa make "cakes" from ground corms of the iris family baked in hearth embers (Deacon, 1984, p. 258), and nomadic pastoralists in northern Ethiopia make unleavened bread by inserting a hot stone into wheaten bread dough that is baked in the hearth (Dufton, 1970, pp. 219–220).

Ancient Egypt

Emmer wheat and hulled barley have been grown in the Nile Valley since the sixth millennium BCE and were used to make bread and beer in Dynastic Egypt until free-threshing wheat was adopted after the conquest of Alexander the Great in 332 BCE (Murray, 2000). Bread-baking practices are known from tomb paintings, miniature models of kitchens and bakeries, statuettes,

texts, excavations of bakeries, oven installations, analyses of preserved bread loaves, and experimental studies (Samuel, 2000). Caution is required in interpreting imagery as "photographic" records, as these artistic renderings were intended for elite burials and likely do not provide details or the range of bread-baking practices. Most evidence indicates that grain was pounded in a mortar, ground into flour on a saddle quern, sieved through baskets, and then mixed with water or milk and sometimes dates, honey, eggs, butter, coriander, sesame seeds, or fruit (Samuel, 2000; Wilson, 1988). Bread may or may not have been leavened, and chemical studies of preserved bread indicate that many were not fermented (Samuel, 2000). Bread products were coarsely textured and caused heavy wear on Ancient Egyptian's teeth (Leek, 1972).

During the Old Kingdom (2686–2160 BCE), emmer wheat and barley flours were baked into bread in commercial ovens that used large conical molds called *bedja*. *Bedja* were stacked and preheated, filled with dough or batter, covered, set into depressions in the bakery floor, and banked with hot embers (Lehner, 1997; and the Giza Plateau Mapping Project <https://oi.uchicago.edu/research/pubs/ar/93-94/giza.html>). Bread molds change from large bowl forms that were thick to retain heat and to prevent the bread from burning to long cylinder shapes by the Middle Kingdom (2055–1650 BCE) that baked bread in a shorter time (Samuel, 2000, p. 586). The latter type of molds had to be broken to remove the bread (Jacquet-Gordon, 1981).

Throughout the dynastic period, bread was baked in domestic kitchens in bread molds baked in box ovens, in clay pans set on top of smaller box ovens; hand-formed loaves were baked in hearth ash, on a stone set in the hearth, in small dome-shaped clay ovens; or dough was baked on the outside of clay oven walls (Wilson, 1988).

During the New Kingdom (1550–1069 BC), emmer wheat predominated and bread was baked in tannur-type ovens that became the main domestic and temple bread-baking technology (Samuel, 1999). Tannur first appear in southwest Asia in the late fourth millennium BCE (Van de

Mieroop, 1997, p. 156) and consisted of a clay cylinder, sometimes set into a bench, with wood, cattle dung, or other fuel fed through an opening at the bottom. Dough is inserted through the top and is pressed onto the hot interior walls to bake. Bread molds were used for ritual purposes in the New Kingdom, and a variety of hand-formed bread shapes were baked inside large commercial domed ovens. Some ovens were so large that the baker was held by his feet to avoid falling into the fire as he reached inside to position dough and retrieve baked bread (Wilson, 1988, p. 55). There were 40 different bread types recorded during the New Kingdom, and the Egyptians were the first to make leavened bread. There is evidence that they had developed a form of pure yeast in barm form likely obtained from beer brewing (Weeks, 2004, http://www.thebanmappingproject.com/articles/article_15.4.html; Wilson, 1988, p. 14).

Ancient, Historic, and Contemporary Middle Nile (Nubia) Bread

Ancient Egypt and Nubia had a long history of colonization and commercial interaction in the predynastic and dynastic periods. This resulted in the spread of wheat, barley, and bread-baking technology from Egypt to Nubia. Jacquet-Gordon (1981) developed a typology of conical bread molds found on Egyptian and Sudanese sites dating from the Egyptian predynastic/early dynastic period to the 25th dynasty (747–646 BCD) when Nubian (Kushite) kings briefly ruled Egypt. Bread molds are only found in Sudanese sites of the Kushite Empire, a period subdivided into the Napatan (ninth–fourth centuries BCE) and the Meroitic (fourth century BCE–fifth century CE). There are differences in the distribution of bread molds and bread consumption in Ancient Egypt and Nubia. Bread molds are found in Ancient Egyptian cemeteries, habitation, and temple sites, and bread was eaten by elite and poor alike. In Nubia, bread molds are found almost exclusively with temples dedicated to Amun (Anderson, D'Andrea, Logan, & Ahmed, 2007), although Haaland (2012) suggests that the elite adopted bread consumption as part of the process

of increasing social complexity in the Kushitic period. Bread was offered to the god Amun, who was believed to consume the bread's essence, and later priests and other appropriate people ate the bread (Anderson & Salah El-Din Mohamed Ahmed, 2006a). Large mounds of ash and broken conical molds are found behind these temples and are sometimes associated with ovens (Anderson et al., 2007).

It is assumed that Napatan period bread was made with flours of emmer wheat or barley (Anderson et al., 2007; Edwards, 2004), but a recent study of bread molds and bread-baking equipment excavated from the Meroitic site of Dengeil determined that sorghum rather than wheat was used to make bread (or beer) in these molds (Anderson et al., 2007). By the Meroitic period, sorghum was the dominant crop of the Kushite Empire, and it was symbolically associated with kingship (Anderson et al., 2007). Bread molds were shaped by hand around a wood form and were produced in two sizes: large (c. 100 ml of dough) and small (c. 30 ml of dough) (Anderson & Salah El-Din Mohamed Ahmed, 2006b). There are no ovens found at Dengeil, and the bread molds are not charred by fire. An experiment showed that the molds could be used to shape *aceda* (soft fermented or unfermented sorghum porridge) (Anderson et al., 2007), which today is molded with a bowl, served on a plate, and eaten with a spoon. Notations on a clay sherd found at Dengeil are interpreted as a baker's record of bread batches or a list of bread ingredients.

Sorghum bread products were baked on clay griddles (*doka*) in the Middle Nile for over a millennium, but *doka* are now nearly replaced by the use of a thin iron griddle (*sadj*). Edwards (1996, p. 71) claims that sorghum bread was not made until the middle of the first millennium CE when *doka* first appear in the Kushite ceramic repertoire. Anderson et al. (2007) suggest a slightly earlier date for *doka* based on the representation of round bread in Kushite offering trays at Meroe dated to the second century CE. These loaves are hand molded and are similar in form to five bread loaves recovered from a Ballaña culture cemetery (fourth–sixth century CE) in Lower Nubia. These round loaves may represent bread

Bread in Africa,

Fig 2 Kissra baking

(Source: Photo Diane Lyons)

prepared on *doka* (Anderson & Salah El-Din Mohamed Ahmed, 2006a). *Doka* are common on medieval Nubian sites (ca. 500–1500 CE) when the region converted to Christianity. *Doka* continue into the postmedieval period, which Edwards (2004, p. 385) attributes to new Islamized and Arabized elite influences that include wheat and bread culture.

Many varieties of sorghum and wheaten bread continue to be produced on griddles in the Middle Nile today (see below), and their distribution is determined by cropping patterns. Wheat and barley are grown in the northern part of the Middle Nile, and sorghum predominates in the south. *Kissra* is staple pancake bread made of fermented or unfermented sorghum or finger millet batter on griddles. *Doka/sadj* are balanced on three stones or set into a clay bench over a hearth fueled with animal dung, small pieces of wood, or other dried plant matter (Dirar, 1993, p. 171). In the Delgo region, women make bread (*gerasa* and *sensana*) with fermented or unfermented wheat or barley flour dough although barley is considered inferior for bread making. The *doka/sadj* are wiped with an oily cloth to lubricate the surface before and during baking (see Fig. 2). At least eleven different types of Sudanese sorghum or sorghum-based breads are produced including a thin wafer called *abreh* of fermented sorghum dough that is boiled into a thin porridge before it is spread paper thin on the hot griddle. The resulting wafer bread is made into a beverage, and a spiced and dyed

version (*hulu mur*) is served at Ramadan. Women also make small clay-domed ovens in their kitchens to bake wheaten loaves (see Fig. 3). Commercial bakeries in urban centers have much larger domed ovens made of baked brick for the production of wheaten bread (*aish baladi*, similar to pita bread). These ovens are heated with wood fuel placed on one side of the oven, and flat bread dough rounds are positioned on the other side of the oven using a wooden paddle (see Fig. 4).

Other baking technologies are reported for eastern Sudan. Thick sorghum porridge is baked into small flat bread called *hadib*, on the inner preheated walls of earthenware pots or metal petrol cans similar to tannur (or *mofa*, see below) (Dirar, 1993, p. 220).

Horn of Africa

Bread is a staple food in the Horn of Africa. In northern highland Ethiopia, bread was a dietary staple by Aksumite times (300 BCE to 800 CE) when huge quantities of bread were taxed from rural households (Kobischankov, 1979). No definite bread ovens are known from the highlands, but clay griddle fragments similar to *mogogo* (Tigrinya) or *metad* (Amhara) were found with evidence of domesticated t'ef, emmer wheat, and barley dated to 500 BCE near Lake Tana (Dombrowski, 1971). However, evidence of

Bread in Africa,**Fig. 3** Domestic bread oven (Source: Photo Diane Lyons)

B

Bread in Africa,**Fig. 4** Commercial oven baking aish baladi (Source: Photo Diane Lyons)

mogogo is found only in Aksumite deposits after the sixth century CE (Phillipson, 2012, p. 110). *Mogogo* are found with Black Ware in the Asmara region in Eritrea by the late first millennium CE (Schmidt & Curtis, 2008) and may be associated with the Beja (pastoralists from eastern Sudan) who are hypothesized to have migrated into the Asmara area at that time. Although archaeologists focus on *mogogo* as evidence of bread making, it is not the only griddle used for this purpose. In eastern Tigray Ethiopia, bread is made also on very thin basin griddles (*meklo gundo*, 2–3 mm thick) (Lyons, 2007), which are fragile and may not be preserved (or be recognized as griddles) in archaeological deposits.

In northern highland Ethiopia and Eritrea, contemporary *mogogo* are ca. 60 cm in diameter and are set on top of a firebox of upright, clay-covered stone slabs with an opening to the front for feeding fuel of cattle dung and small branches. In the central and southern highlands, *metad* are balanced on three stones set over a fire. Griddles are lightly lubricated with crushed oily seeds, and removable dome-shaped covers are sometimes used to steam the bread (Lyons & D'Andrea, 2003). Many types of bread are produced. *Injera* is made from flours of *t'ef*, finger millet, wheat, barley, sorghum, pulses, and more recently maize and is served with most meals (Lyons, 2007; Lyons & D'Andrea, 2003) (see Fig. 5). Viscous bread dough made with flours of wheat, barley, or

Bread in Africa, Fig. 5 Injera baking on a mogogo (Source: Photo Diane Lyons)

Bread in Africa, Fig. 6 Bread baking on leaves on a mogogo (Source: Photo Diane Lyons)

sorghum grains is also baked as flat bread or slightly leavened bread on the *mogogo*, including bread made of malted barley or finger millet used in beer brewing. Thick leavened wheaten loaves (2–3 cm) are placed on leaves or succulents that serve to flavor the bread and to prevent the bread from burning (see Fig. 6). Some bread types are steamed by sealing the *mogogo* cover to the griddle using fresh cow dung or clay. Steaming improves the crust and helps leaven the bread. In eastern Tigray, *mogogo* are also set inside special pots (or more recently metal drums) on an interior flange or over stones. Water is poured into the bottom of the pot below the *mogogo* (or metal tray), and the pot is set over a fuel source to steam the bread. In the southern Ethiopian highlands, *injera* and different varieties of flatbread are prepared from the fermented pseudostem of *Ensete* and other tubers (Arthur, 2014; Smeds, 1955, p. 24). Shack (1974) also reports that Harari produce a staple sorghum loaf called *uxat*, but no information is provided on its preparation. Bread ovens are not found in rural kitchens, and the

commercial bakeries that produce European style bread were introduced to Ethiopia and Eritrea in the twentieth century (Pankhurst, 1968, p. 712).

Injera is a dietary staple in Djibouti and is the same as Ethiopian *injera* and made of *t'ef*. Somalia has different types of bread (Abdullahi, 2001, p. 113). In the north, *injera* called *lahoh* is made of sorghum flour batter poured onto a well-oiled griddle. Sweet *injera* and bread made with eggs are also produced. Thick sorghum dough is baked into flat bread on an oiled pan, and “Swahili” sorghum (or maize) flour bread (*muufo*) is baked in a tannur-type oven (possibly a *mofa* oven; see below) along the southern Somalian coast. Indian influences from Somalia’s long participation in the Indian Ocean trade include *roti* bread made in commercial ovens in towns.

Northern Africa

Wheat and barley were grown in North Africa since the mid-first millennium BCE, and sorghum

and pearl millet were introduced into Libya during the early Islamic period (Pelling, 2003). Northern Africa was an important wheat-producing province for Rome, and the analysis of Roman diets in skeletons recovered at Leptimus, Tunisia (Keenleyside, Schwarcz, Stirling, & Lazreg, 2009), indicates that the population's diet was dominated by terrestrial products that would have included bread. One method for bread production in Roman North Africa is a portable clay pot oven (*cilbanus*), the remains of which are found in Roman Tunisian sites (<http://blog.britishmuseum.org/2013/07/19/a-very-versatile-roman-oven/>). Sally Grainger's experimental work demonstrates that the *cilbanus* is an efficient means of cooking many different dishes including bread by placing the food inside the pot and heaping hot coals around and over the lid. Bread can also be baked on the tray part of the *cilbanus* over radiant heat. Today, in large villages in Tunisia, leavened wheaten bread is made in commercial tannur-type ovens, and griddle cakes (*kesra*) are baked in a dish or on a metal plate. Griddle bread and pancake are sometimes stuffed with vegetables, meat and fruit, or a spicy sauce (Balfet, 1975).

In the High Atlas Mountains of Morocco, bread flours are made of wheat, barley, maize, millet, and sometimes acorn (Balfet, 1975; Bruneton, 1975). According to Bruneton (1975), women make ovens (*afarnu*) by piling small stones 50 cm high and 80 cm diameter at the base, and the pile is coated with thick clay. When the clay dries, holes are cut at the top and the base and the stones are removed. The base of the oven is made of flat stones set over rock salt to retain heat. Bread types include leavened wheaten bread for feast days and barley loaves for daily eating. Once the oven is heated, coals are swept to the side, and leavened bread dough is placed on the oven floor. Unleavened dough is baked on a hot stone plate or pottery sherd balanced on two stones over a fire (Bruneton, 1975) or on ceramic plates (griddles) called *makla* that were placed on the hearth (Peña, Peña-Chocarro, Estévez & Urquijo, 2003). Dough is flavored with herbs, oil, garlic, onions, dill, sesame, and aniseed (Balfet, 1975; Bruneton, 1975).

Sahara

Excavation of houses from settlements of the Garamantes Polity (ca. 500 BCE to 500 CE) in the Fezzan region of southern Libya determined the presence of hearths, pottery, grinding stones, and cereals but no evidence of bread baking. Medieval period records of Islamic and North African travelers remarked on Saharan Berber population's bread consumption (Lewicki, 1974). Bread in pancake form or hard biscuit was made from flours of millet, sorghum, tubers, and wild seeds. Bread made of tuber flours was reported as a staple for the Zaghawa, but baking technologies are not described. Today tannur ovens are found in courtyards of historic and contemporary rural houses in the Fezzan region (Mattingly, 2003).

The Tuareg of the Central Sahara are believed to descend from the Garamantes. Wheaten bread is common in the diet of northern Tuareg and is baked in hearth ash, on a metal baking sheet, or on the sides of an inverted metal pot heated over the fire (Nicholaisen, 1963). Tuareg make millet flour bread (*taguella*) that is baked in a preheated shallow depression in the ground. Fine sand and hot coals or a small fire is set over the top to bake the batter through (Gast & Adrian, 1965; Nicholaisen, 1963). Wheaten bread is washed, broken into pieces, served with liquid butter, and eaten with spoons; *taguella* is served with a sauce. *Taguella* may be the bread described by Ibn Baṭṭūṭa as *tekoula*, a hard biscuit used to provision trans-Saharan trade caravans from Timbuktu to North Africa (Lewicki, 1974, p. 160). Tuareg women produce medicinal bread for their own consumption made with millet flour, berry juice, and special plants. These ingredients are mixed with water into a cake and baked like other millet bread (Nicholaisen, 1963). Similarly nomadic pastoralists in Sudan and Egypt use larger earth ovens with floors of heated pebbles or pot sherds to bake sorghum or millet flour dough (Dirar, 1993, p. 218; Hobbs, 1989).

East African Coast

Ovens called *mofa* occur in ninth-century AD houses at Shanga on the Kenyan coast, and the

ovens were used later on Arab dhows (Horton, 1996, pp. 46, 353). *Mofa* consist of clay bowls set in floors that were possibly used to bake bread and boil liquids (Horton, 1996, Plate 21). At the nearby site of Manda, *mofa* were made of clay cylinders of ca. 40 cm in diameter with no base and were constructed inside a pit (Chittick, 1984, p. 153). The cylinder was then surrounded with soil and a fire was lit inside and sorghum or millet flour dough was baked on the hot interior walls. Twelfth-century Chinese traders describe this bread as a dietary staple (Horton, 1996, p. 353). Horton (personal communication, 2005) observes that *mofa* are concentrated in northern Swahili coastal sites where sorghum is consumed and are much less common on southern coastal sites where rice is eaten. Although *mofa* are similar to *tannur*, Horton suggests that this simple technology could be a local invention. This bread type apparently extends geographically to Somalia (see above).

West Africa

McIntosh (1995 pp. 159–160) suggests that bread may have been made at Jenne-Jeno in Mali 2,000 years ago from pearl millet and sorghum flours using earth depressions similar to those of the Tuareg. A millennium later, medieval travelers observed bread consumption in the Central and West African savanna states from Lake Chad to Africa's West Coast (Lewicki, 1974). Medieval Arabic travelers describe pancake and bread made with millets and tubers in Jenne and Gao that were consumed either as luxury items or cheap traveler's fare (Lewicki, 1974, pp. 46–47, 80). Fritters made of fried millet dough were described as common in Bornu (northern Nigeria/Cameroon) as well as in areas farther west. Unfortunately baking technologies are not described. Today round clay griddles with four to six small bowls are used to fry fermented batter of pearl millet flour into small cakes called *masa* or *marsa* in Ghana (Apentiik, 1997) and Mali. Guinea millet is also made into fritters and cakes in northwestern Guinea (National Research Council, 1996, p. 237).

Colonialism and Globalization

European colonization brought wheaten bread to sub-Saharan Africa. Colonial regimes denigrated African culture as inferior to their own, including African culinary practices based on sorghum and millet cereals. In French West Africa, European style bread was introduced by the early twentieth century, wheat was imported, and bakeries were established in coastal centers (Mosley, 2004). As urbanization expanded, indigenous acceptance of bread increased, and it was perceived as modern and more sophisticated than sorghum and millet porridge. Mosley (2004) notes that colonial regimes acted differently. In Spanish Equatorial Guinea, Africans were not allowed to eat European food including bread until they demonstrated a level of cultural assimilation. However, as the demand for bread increased in cities, African colonies and postcolonial nations became entangled in the "wheat trap," a phenomenon in which sub-Saharan nations became dependent upon imported Western wheat at the detriment of indigenous crop production (Kimmage, 1991; Mosley 2004). Food scientists continue to develop methods to produce leavened bread with African cereals as a measure to protect African crop production and reduce reliance on imported wheat (National Research Council, 1996).

Brewing in Africa

John W. Arthur
Tampa, FL, USA

Beer in Africa has been an important food staple since the Old Kingdom of Egypt (5400–5500 BP), from the site of Hierakonopolis (Geller, 1992; Maksoud, El-Hadidi, & Amer, 1994) and the New Kingdom of Egypt (1550–1070 BCE), to workmen’s village sites at Amarna and Deir el-Medina (Samuel, 1996). In many cultures of Africa, beer provides a substantial part of the diet, with one-eighth to one-third of grain crops being processed and consumed as beer (Platt, 1964). Beer socially binds people together and serves to reinforce social hospitality, usually without aggressive behavior or addiction

(Mandelbaum, 1965). African societies use beer to indicate wealth and status, as a commodity of reciprocity, hospitality, and communality, as a payment of tribute to leaders, and as a vital food for the redistribution of wealth (Arthur, 2003). In some cases, colonialism has dramatically changed the structure of beer and its ties to society. This paper reviews the importance of beer in Africa based on a number of ethnographic case studies.

Beer Production

The production of beer in Africa is usually under the domain of women. It requires a considerable amount of time-consuming labor. In most societies, producing beer is a multistep process. For the Mabaso women of South Africa or the Maale of southern Ethiopia, beer production can range from 5 to 12 days (Donham, 1999, pp. 153–155; Reusch, 1988, p. 24). First, women let the grain sprout in a damp pot to produce a malt and then mix it with additional grains, and grind on a stone for hours. They bring large quantities of water from up to a mile away to mix with the ground grain and then boil the malt and flour in large pots. After boiling the mixture, women ferment the beer in large gourds or ceramic vessels. In Tanzania, the Haya make a beer using a combination of bananas and sorghum (Carlson, 1990). They use ripe bananas because of their high sugar content, which assists in the fermentation process. The bananas are mashed with the help of dried grass, and then water is added in equal proportion to the banana liquid. After the water is added, dried sorghum is mixed into the water and banana solution and left to ferment for 24 h. In Ethiopia, the Gamo produce beer by two different methods (Arthur, 2000). The highland Gamo produce beer by boiling water in a large ceramic cooking jar and then pouring the water over the wheat and barley flour and stirring it in a large serving bowl, where it is left to cool. It is then poured into a beer jar to ferment for 4 days. The second way to produce beer, which occurs in the lowland areas, is to combine and boil water and flour and then

store this mixture in large beer jars for fermentation (Arthur, 2000, 2002, 2003). In the majority of societies, women produce the beer, but once they produce it, it is used by many segments of society.

The Social Consumption of Beer

In Africa beer is consumed every day as a food product and beer also plays an essential role in the establishment of social obligations. The importance of communal consumption is one of the reasons people process their grains into beer rather than bread (Dietler, 1990). Beer is often considered a food, rather than a beverage, and the consumption of beer adds considerably to their daily calories (Gardiner, 1836, p. 266; Green, 1999, p. 414; Haggblade, 1992, p. 395; Karp, 1980, p. 85; Moore & Vaughan, 1994, p. 192; Richards, 1939, p. 80; Saul, 1981, pp. 746–747). Beer may contribute to increasing caloric intake, but its symbolic role may be more important than its nutritional role. However, de Garine (1996, p. 215) argues that beer “may be richer in vitamins PP and B-12, phosphorous and calcium than sorghum porridge, but it contains only half the calories, one-quarter of the proteins and no glucids” (Adrian & Sayerse, 1954, p. 136; Pele & Le Berre, 1966). For example, among the Koma of northern Cameroon, sorghum beer provides one-third the total energy consumed in a year and bonds age-sets and establishes a hierarchy between each one (de Garine, 1996, p. 210). Among the Tiriki people of Kenya, beer is offered to visitors as a sign of friendship (Sangree, 1962, p. 11), and the Baganda of Uganda use beer as a way to bond two men socially (Robbins, 1979, p. 371). Beer acts as a social lubricant when the Tiriki and the Iteso people of Kenya men sit around communal beer pots everyday to discuss social issues, disputes, and tell stories (Karp, 1980; Sangree, 1962). The Haya of northwest Tanzania pay respect to fathers by offering them a gourd of banana beer, which must be done before others can be served (Carlson, 1990). In addition, the Haya will offer a sacrifice of a gourd of beer to a father at the ancestral altar. The Kofyar of northern Nigeria

conduct all aspects of their daily life around beer (Netting 1964). The Kofyar use beer as an award and as a punishment against not taking part in work parties, verbal or physical violence, disrespect of a clan member, or minor theft.

Beer as a Motivating Ingredient

In order to gather a work party, beer is essential; without beer, it is impossible to bring people together to cooperate on the task at hand. Work feasts are a type of commensal politics (Dietler, 2001; Dietler & Herbich, 2001), where people organize to work on a specific project and in return receive beer for their labor. Beer in work parties provides a social alliance between the work party sponsor and the people involved in the work party. Beer changes the context of the group, by becoming the “social focus” for all of the work party members, but also for people associated with the party members (Donham, 1999, p. 155). Among the Konso of southern Ethiopia, the quality and quantity of beer is a motivational force in gathering people for a work party (Watson, 1998, p. 148). If a person produces a high quality beer in sufficient quantities, then they can expect a range of 20–50 people to help them in the fields. There are a number of different types of Konso work parties, which involve fixed or volunteer groups, costing the sponsor approximately 50–150 Ethiopian birr (US \$7.00–\$21.00) depending on the size of the work party. Feasts also accompany work parties, as in Southern Africa, where leaders and wealthier commoners organize large work parties and then provide an abundance of beer (Crush, 1992). The Pondo of South Africa rate their beer feasts higher than meat feasts, because beer makes the work seem more like a party (Hunter, 1979, pp. 89–90). Among the Kofyar of Nigeria, beer is the primary means for repaying voluntary labor to hoe and harvest agricultural fields and for building corrals and houses (Netting, 1964). These examples demonstrate that beer is a motivating force for labor and beer also has a role to play in the formation of the elite.

The Social Hierarchy of Beer

The payment of tribute with beer indicates its economic and political importance. Although beer in Haya society is a secular refreshment, it has symbolic value since when Haya men make banana beer they must be sexually abstinent while brewing the beer (Carlson, 1990, pp. 298, 303–304). When the Haya produce beer, it is their obligation to pay their leader four or more gallons of banana beer. Beer, along with livestock, barkcloth, and iron products, are presented to leaders as tribute. They present the leader with special gourds of beer that have wrappings of banana fiber covering the gourds which are tied with twigs and leaves from a plant that symbolizes purity and strength. As with the offering of beer to the deceased father, the Haya king also offers a sacrifice to his ancestral altar for the welfare and fertility of his kingdom.

The Chagga leaders of Tanzania opened their houses and gave generous supplies of beer, which fulfilled their redistributive obligations and supported the warriors, who would fight on their behalf (Dietler, 1990, pp. 370–371; Gutmann, 1926, p. 346). The Chagga leaders would collect this beer through either a tax that the people were happy to pay so that they might socialize with the leader or through a work party in which people would help cultivate his millet crop, which was used to make a beer feast. A sign of a good Buganda leader is the redistribution to the people in the form of “beer, meat, and politeness” (Mair, 1934, p. 183). As with the Chagga, the Buganda leaders obtain their beer through a tribute system and beer also is used to settle disputes as fines (Robbins, 1979, p. 371). Thus, the payment of beer forms a social, economic, and political reciprocal bond between commoners and leaders.

Brewing beer in association with slaughtering cattle among the Koma of Cameroon also provides a means to improve an individual’s status (de Garine, 1996, pp. 208–210). The cattle dance ceremony celebrates the hard work and good qualities of a man’s wife as being a good mother to their children. The ceremony in her honor is a redistribution feast that increases the husband’s social status by distributing meat and beer to their

kin and religious leaders. Once the husband has hosted up to seven ceremonies his status increases because he is knowledgeable about the secret rituals and places and can drink beer from his own pot without sharing.

Beer is associated with the wealthy, high-caste Gamo households (Arthur, 2003). The political and religious aspects of Gamo life are under the authority of the *mala* caste. The production and consumption of beer occur at all political and religious ceremonies such as at initiation feasts for ritual-sacrificers (*halakas*), weddings, and at ceremonies celebrating saints' days. The *mala* ritual-sacrificers must demonstrate their generosity through beer feasts. The wealthiest *mala* are "caught" by the other *mala* members to become ritual-sacrificers (*halaka*) (Halperin & Olmstead, 1976). If the people choose a person to become a ritual-sacrificer, his duties are to perform animal and beer sacrifices in which he prays for the health and fertility of his people, crops, and animals. Gamo ritual-sacrificers are always men, who must be circumcised, married, wealthy, and morally respected (Sperber, 1975, p. 215). However, to become a ritual-sacrificer, a person has to perform two beer feasts (*perso oosha*), which include producing enough beer for the people who reside in his political region (*dere*) (Freeman, 1997). This ritual-sacrificer must have enough farmland to provide for producing large amounts of beer and other types of high-status foods. This redistribution of wealth cannot be refused by the chosen ritual-sacrificer (Sperber, 1975). He must organize two different feasts, one at his house and the other in the area of community gatherings (Freeman, 1997). At both feasts, the participants must wait to start drinking until the *halaka*-to-be and the elder-sacrificer pour beer on the ground as an offering for the spirits. Each redistribution feast can comprise up to 300 people and requires 800 kg of wheat for beer production (Halperin & Olmstead, 1976).

Thus, beer in African cultures is more than just a beverage; it is a critical component to the social, economic, and political structure of society (Carlson, 1990; Netting, 1964; Robbins, 1979; Sangree, 1962). People spend a considerable amount of their labor and time processing their

crops into beer rather than bread because of the value of beer in establishing alliances. Beer binds these different groups together by providing a means of establishing reciprocity in the form of labor and social and economic coalitions. Furthermore, the importance of beer in the form of symbolic respect to the living and to ancestors exemplifies its significant role for the well being of societies (Arthur, 2003).

Bricks in Nineveh

Davide Nadali

Dipartimento di Scienze, dell'Antichità,
Sapienza Università di Roma, Rome, Italy

Nineveh was completely rebuilt, restored, and enlarged when it was elected as the capital city of the Assyrian empire by the king Sennacherib (704–681 BC) in the seventh century BC. He had finally abandoned Dur Sharrukin, the city founded by his father Sargon II (721–705 BC).

Sennacherib deeply changed the aspect of Nineveh. The city was an important urban center since the most ancient period because of the presence of the temple dedicated to the goddess Ishtar. During the Assyrian time, the city always had a significant role because of the Temple of Ishtar, but it finally acquired a new political status when it also hosted the seat of the Assyrian kingship. In the seventh century BC, after Sennacherib, Nineveh kept the role of the Assyrian capital of the empire as it did also during the reigns of Esarhaddon and Assurbanipal. In the last phase of Neo-Assyrian history, Nineveh underwent major works of restoration of old structures and construction of new buildings. The building activities are in fact largely described and registered in detail in the Assyrian royal inscriptions. Precise accounts are given of the building projects by King Sennacherib for the restoration and extension of the defensive walls and urban gates, the

construction of the new royal residence (the so-called Palace without Rivals in the southwestern sector of the citadel of Quyunjiq), and generally the remaking of the whole urban pattern and structure with new roads, bridges, and aqueducts, the control of water sources and rivers, and the realization of botanical gardens (Grayson & Novotny, 2012).

The massive works carried out during Sennacherib's kingdom deeply renewed the aspects of Nineveh. As a consequence, mud bricks were intensively produced to accomplish the transformation of the city during what can be labeled the Assyrian renaissance. They produced technological innovations and knowledge improvements so that the new architectures and visual programs under the reign of Sennacherib were qualified as masterful and artful with no comparisons and rivals (Winter, 2008).

Architectural indications of measurements in the inscriptions refer to the number of bricks used. For the walls of Nineveh, it is said that they were 40 bricks thick and 180/200 brick-courses high; for the construction of Sennacherib's palace, inscriptions say that the height of the mud brick terrace was raised to 180 brick courses. Standard mud brick sizes found during the excavations of Nineveh are about 37 by 37 by 12 cm, and, according to these dimensions, it is possible to reconstruct the original height of the wall of Nineveh (about 22 m with a maximum height of 25 m) and the imposing structure of the terrace of Sennacherib's palace (about 22 m high) (Reade, 2000, pp. 399–400). Bricks were massively produced according to standardized dimensions; there were different types of bricks, particularly for different shapes and decorations. As a consequence, bricks were differently used in the constructions as either part of the elevation of the buildings or the decoration of external façades. In this respect, one of the sides of the bricks was painted and colored with geometrical drawings and representations of humans and animals figures, and, in some special instances, bricks were even molded and decorated with high-relief motifs.

For the technique and manufacture of glazed bricks in Assyria, Assyrian glazed bricks are undoubtedly inferior in quality to the

contemporary and later Babylonian production. Actually, the glaze layer on the Assyrian bricks is in fact so friable (Assyrian bricks in museum collections are characterized by weak colors and they must be handled with great care to preserve the few traces of glaze) that it tends to pulverize readily (Reade, 1987, p. 32). For that reason, in old publications, Assyrian glazed bricks were qualified as painted bricks. However, since glazed bricks were supposed to decorate architectural elements of external façades, it is thus quite possible that the glaze layer was originally adequately created and protected to endure. Indeed, improper restorations made in the past, exposure to the air after excavation, and insufficient protection in museum display surely contributed to the damage of the glaze layer with consequent negative judgments and considerations of the knowledge of the glaze technology by the Assyrians (Reade, 1987, p. 32). Modern analyses and researches on ancient glazed (painted) artifacts can in fact reveal the real technological knowledge of the Assyrians by revealing the existence of ancient varnish to protect the surface of the bas-reliefs, bricks, and tiles that were supposed to be placed on the outside (Verri, Collins, Ambers, Sweek, & Simpson, 2009).

For the nature of the decoration, Assyrian bricks can thus be divided into two main types (Nadali, 2006, 2008): glazed tiles decorated with a complete larger scene on the main face and glazed bricks decorated on either the larger face or the smaller sides with a detail of a scene or a figure (Fig. 1). In this instance, bricks were then assembled and arranged as in a mosaic according to a precise order to finally get the whole image – Aramaic letters on the back of the bricks were used as symbols to guide the correct arrangement (Russell, 1999).

A special category of bricks has been found at Nineveh as part of the original decoration of the Temple of Ishtar on the main hill of Quyunjiq. The glazed tiles, probably dated to the reign of Esarhaddon (681–669 BC), are characterized by high-relief vegetal, animal, and human motifs (Nadali, 2008). The single tiles were thus arranged with one next to/above/below the other accordingly in forming the name of the king Esarhaddon written through the use of the Assyrian system of

Bricks in Nineveh, Fig. 1 Glazed tile of Esarhaddon from Nimrud (Photograph taken by the author; reproduced courtesy of the trustees of the British Museum)

hieroglyphic script. The same hieroglyphic writing had been used by Sargon II on the façade of the Temple of Sin at Dur Sharrukin (Nunn, 1988, pp. 175–182); as the bricks of Nineveh, the tiles of Sargon II had on their surface a detail of a larger figure, but the surface was flat. In the seventh century BC, a new shape was introduced: high-relief bricks probably conveyed the long-lasting tradition of molded bricks of central and southern Mesopotamia since the second millennium BC. Esarhaddon's politics in the South, with special sets of building activities at Babylon, probably influenced the Assyrian way of making bricks, or, conversely, it might be inferred that Babylonian craftsmen worked at Nineveh following their tradition in shaping bricks with high-relief pictures (Nadali, 2008) (Fig. 2).

Mud bricks were the basic material for construction in Assyria, as generally in all regions of the ancient Near East. The numbers of bricks, as referred to in the Assyrian royal accounts, indirectly indicate the dimensions of the buildings, showing how the brick was a kind of standard unit for measurement in building activities.

Bricks in Nineveh, Fig. 2 Glazed high-relief brick of Esarhaddon from Nineveh (Photograph taken by the author; reproduced courtesy of the trustees of the British Museum)

Glazed bricks and tiles were suitably used in particular context of the architecture to highlight architectural elements and decorate external façades of both temples and palaces. The glaze layer gave bricks and tiles a shining appearance, and this probably was the main aim in using these colored and brilliant materials in the constructions. Façades of temples and palaces were immediately recognizable even from a distance; the colors and light of the glazed bricks radiated the power and *melammu* of the gods and kings of Assyria. Temples and palaces were built on high terraces. The palace of Sennacherib at Nineveh stood on a terrace 180 brick-courses high; the Temple of Ishtar at Nineveh was also built on the top of an artificial terrace. Both buildings emerged from the line of the city walls, and colored glazed bricks distinguished the seat of the goddess and the seat of the king from the rest of the public buildings of Nineveh.

Buddhism and Science

Somparn Promta

Buddhism is normally viewed as an atheist religion. Modern interpretations of the Buddhist teachings made by Buddhist scholars in South-east Asia seem to bring Buddhism close to what is called 'science' in the modern world. That is, Buddhism is explored as a religion teaching that human life, the world, and the universe are the *Dhamma*, a Pali word containing complicated meanings. According to Buddhadasa, the most famous Thai Buddhist thinker, the Dhamma has four meanings (1) natural things, (2) natural laws, (3) human obligations to follow natural laws, and (4) the fruits gained from following the laws of nature. So human life, the world, and the universe, according to Buddhism, are natural things in themselves and they follow the certain laws of nature.

In Buddhist perspective, natural things and natural laws are not created by God or any other supernatural power. They exist naturally, meaning that the concept of creation is not necessary. However, Buddhism does not stress the philosophical arguments concerning the origin of the universe. The view of Buddhism on natural things and natural laws is practical in a sense that knowing what is the world *as we see now* should lead to a happy life. It should be noted that Buddhism believes that religious practice is closely connected to the laws of nature, so the learning of religious teachings in Buddhist perspective is learning the laws of nature.

In Buddhist texts, five laws of nature are mentioned (1) physical law, (2) biological law, (3) psychic law, (4) *kammic* law, and (5) moral law. The first two laws are believed by Buddhist scholars to be the same laws explored in physics, chemistry, and biology in modern Western science. Psychic laws could be partly compared to what are called psychological laws in Western psychology. However, there are some special contents in the Buddhist psychic laws not found in Western psychology. An example of these is the cultivation of the mind through meditation. Kammic laws are the laws concerning human actions. Buddhism believes that what we are is directly the result of what we do. We are born as a free entity to choose our future freely. Philosophically speaking, Buddhism believes that we are born with a free will. In this sense, we are solely responsible for whatever we have done. *Kamma* or Karma in Buddhist teaching, an action with intention and carrying moral value, is a secret power, like the field in physics, which dominates our life. Good Kamma determines a good life; bad Kamma determines a bad life. Moral laws are the laws that govern any events that cannot be classified under the first four laws. For example, Buddhism believes that the unjust or immoral structure of society is a bad thing. It is bad according to moral law. It is possible that individuals in society act well according to the law of Kamma, but they are good people in a bad society. The Buddha is well known as arguing against the caste system in ancient India. For him, it is possible that people of each class act well

according to their class duties, but caste is still a bad thing, judging from moral law.

Looking through the Buddhist five laws of nature, we can see that the belief in nature is wider than the belief in nature found in science. In Western science, the laws of nature as found in physics, chemistry, and biology have nothing to do with social justice, fair distribution, or the violation of human rights. Science within this tradition has become something containing a narrow meaning. Science never questions how we can gain a happy life or a just society. Typical scientists seem to think that such a question should be considered outside the scientific community. It should be part of political science or political philosophy. The above tendency leads to the separation between 'knowledge' and 'value', and between 'nature' and 'human convention'. The Buddhist conception of natural laws does not make the same separation. For Buddhism, physical and biological laws are the beginning laws of nature to be explored. They are looked on as a means leading to some things more valuable.

Between human life and the physical world, Buddhism thinks the former is of more importance. However, as our life can never be separated from the world, the study of the physical world is accepted by Buddhism to be of some value as far as it is undertaken in balance with the study of human life. Furthermore, the study of the physical world must not be run separately from the study of society. If we are allowed to call the activities of exploring nature through the Buddhist five laws 'Buddhist science', what follows is that Buddhist science stresses the balance between three things: human life, society, and physical world.

The confrontation between modern science and Buddhism in the Buddhist countries such as Thailand seems to be best understood in the light of the Buddhist conception of nature as said above. In Thailand, where Theravada Buddhism plays the role of a national religion, the sale of GM food is allowed by law under the condition that the products must be declared to contain GM ingredients. Buddhism in Thailand does not raise moral questions about this, while Islam seems to doubt it. The recent study of the opinions of Buddhists concerning the issues of human

cloning and stem cell research in Thailand declares that the Buddhists, compared to Christians and Muslims, can more easily accept human cloning and the use of stem cell for medical purposes if it is proved safe. This phenomenon can be understood if we are reminded that Buddhism is a religion free from religious dogmas. Like science, Buddhism believes in the natural creation of things. For Buddhism, anything allowed to happen in the world is 'natural'. So, Buddhists do not view human cloning as unnatural. On the contrary, it is 'natural' in a sense that it is allowed by the second law of the five laws. However, it should not be understood that Buddhism has nothing to question about these issues. These arguments essentially stem from the conception of balance between the five laws. Human cloning and stem cell research are viewed as activities run within the second law. So, it is not isolated from other laws.

Finally, Buddhist scientists in Buddhist countries like Thailand seem to feel that Buddhism and science are friendly. This feeling possibly stems from the picture of Buddhism in their minds. Buddhism as taught in the university classroom shares a lot with science. In chapters of high school Buddhism textbooks, the way the Buddha searches for knowledge is usually described in terms of scientific enquiries. The Buddha says that he did not create the truths he found after the process of study. They were naturally given. Anyone, according to the Buddhist perspective, can be a Buddha. The term 'Buddha' means the one who is enlightened. Enlightenment is nothing but the realization of natural laws. Knowledge in the Buddhist view is in the end the same thing as morality. We can easily find the balance between knowledge and value in Buddhist science.

Building Construction

Norbert Edwin Wilhelm
Wolfenbttel, Germany

It is difficult to talk about the differences in Western and non-Western building technologies, as many approaches used today in this field were also used in Western countries in the past. Some, such as mud technology, are currently being revived in Europe. A more appropriate expression might be indigenous or traditional technology.

Some basic approaches, such as the construction of walls out of stonemasonry, mud, or branches plastered with mud, can be found in many places in the world. It is not surprising that there is not so much basic difference, as the construction materials had to be found in the surroundings. What is amazing is to explore which quality or intelligence is presented in the specific adaptation to the climate and in resistance to disasters.

Traditional Construction Technologies Are Still of Great Value

The fact that we now use other technologies does not mean that traditional knowledge was primitive.

Dealing with local material is more ecological, and these old technologies have no recycling problem.

Traditional technologies went through a long process of evolution, so they are in most cases the very best solution, taking into account what basic materials were available at any given place and time. They are well adapted to the local climate and are rather safe with regard to recurring local hazards. However this is only to the extent that was possible with the available materials and knowledge. The typical empirical way of improving the design could respond only to events with a reasonably short recurring period.

Modern technology has to an extent not yet proved its durability. We face problems, like corrosion in prestressed concrete bridges, whereas stone arch bridges survived for centuries without even regular maintenance or repairs. None of the modern bridges in steel or reinforced concrete would ever have such durability.

Many of these old building technologies still have a potential for improvements, if modern materials and knowledge could be added in a sensible way.

Today traditional building technology is for the poor; it is often the only one they can afford and handle. Unfortunately this gives it a bad image. It has become the technology of the lowest classes, seen as being primitive, in spite of all its values and potential.

Some famous architects have discovered the value of traditions and have gotten inspiration from local buildings. Considerable literature about vernacular architecture has emerged, praising the so-called genius loci (sense of place). An excellent collection which shows how people live is Oliver's *Dwellings* (2003). Unfortunately most literature looks purely at the architectural aspects, so that the engineering experience and the intelligent use of materials including their ecological aspects and their climatic adaptations are left out. This is what this chapter will concentrate on. One should not see the genius loci as something mystical; it is an experience that is presented by traditional buildings, and it is important to document the technology in better detail, so that it does not get lost with the death of the last craftsmen.

Tradition Goes with Esthetics

Transport of nonlocal material was too expensive; this led to a rather great uniformity in a specific region. And as buildings and other constructions are unengineered, there is also not much variation in the structure. As a result, traditional buildings are rather uniform. The limitations given today by town planning regulations with regard to the size and often with the specification of certain exterior materials were more or less imposed by the limited resources for the old construction methods.

Limiting the variations of the buildings has a great esthetic advantage. Total uniformity is boring; too many differences in aspects and the missing of a common idea make the built environment chaotic. This is not surprising; all building was based on the variations of plants, landscape, and textures of the available materials. The grain of a piece of wood never is uniform, but it follows a certain law, a certain pattern. No piece looks like the other, yet we still can say what type of wood it is. A landscape has its character, and a forest has its own appearance and mixture of trees. No person looks exactly like someone else. We are used to such variations generated by certain mechanisms, and we appreciate them.

You can analyze this hypothesis when you visit a medieval town in Europe or if you walk through an old Indian city like the historic part of Ahmedabad or an oasis in the desert. There are prevalent materials and variations of the design, based on traditions, limitations of the structural system, and what the owner could afford. Such an appearance corresponds to the older people's experience with their surroundings, and we find it pleasant. A similar homogeneity is difficult to achieve in today's architecture: normally, styles vary too much, or completely new quarters or towns are too uniform. Today one can find as really bad examples totally uniform quarters at the one end or assemblages of what people think are landmark designs, resulting in chaotic shopping malls at the other end.

Valuable Experience Is Conserved in Traditional Buildings

Our modern design work is to a very large extent based on mathematical models and calculations, which give reasonably reliable results for the dimensions and make nearly every shape possible. The old builders did not have such comfortable design tools. They were lucky if they could cope with the geometrical questions in the case of more complicated buildings. The construction of the building with regard to structural problems and in order to provide an optimal climate under the given conditions and restrictions was based on experience. That means testing at the scale of 1:1 at the real building. However, throughout history, traditional technologies were perfected bit by bit. The choice of material was limited to what could be found locally. So stones, mud, wood, and leaves are prevalent in construction technologies.

A limited range of materials is easier to handle in an improvement process. The results we can see today are quite intelligent and efficient. They represent the experience of hundreds or sometimes even thousands of years. For example, in earthquakes, sometimes traditional buildings behave very well and are most efficiently designed, as one will see further below. What is not surprising, but really remarkable, is the climatic adaptation. If you follow the design criteria for comfort in a certain region, you end up normally with the traditional building layout and detailing (Koenigsberger et al., 1973; Lippsmeier, 1969).

However, there are several problems with traditional construction. As it is not based on theoretical models, average craftsmen and engineers do not really know why it works. So one has to follow the old rules, which get more and more lost. Only a few bright people brought the methods forward in the past. All the others were only followers.

The Major Construction Elements

There are many similarities between traditional construction technologies in non-Western

Building Construction,
Fig. 1 Wattle and
 daub wall

B

countries and historical constructions in Europe. Either there was an exchange over wide distances in early times or the availability of material dictated similar solutions. Most likely both were true. However some tropical areas had their own specific solutions, mainly dictated by the different climate and available materials.

Walls

Walls, the most important construction elements, are mainly of the following types:

1. **Wattle and daub.** The basic structure consists of wooden posts, normally directly put into the ground or in a simple foundation. In some regions the ends of the posts to be placed in the earth were slightly burnt until they developed a charcoal surface that made them a bit more resistant to rot. A grid of smaller branches or bamboo, normally bound together by plant fibers, filled the space between the posts. The infill could also be of stronger horizontal branches and vertical hatch or wooden weaving. This wooden core was covered on both sides with mud. Sometimes fibers like short cut straw were added (Figs. 1 and 2).
2. **Mud formed in situ.** Here the mud is mixed with water until it becomes workable. This is often done with the help of an ox walking in the mud. Then the mud pieces are placed one over the other while still wet and made smooth.
3. **Sun-dried mud bricks.** After forming and drying bricks of wet mud, they are joined together with mud mortar.
4. **Rammed earth.** Here only slightly moistened and rather sandy soil is rammed in forms of varying sizes in layers. High buildings up to five stories are built with this method. Well-known examples are the houses in Sanah, Yemen, and the famous mosque in Mopti, Mali. In Europe large and high buildings still exist, made of rammed earth; it used to be a widespread method in Southern France.

This wall type is probably used the most in the world. The method of infill is also used for the typical European timber framework. One can

achieve a very smooth surface if the last layer is reworked over and over without letting it dry until all shrinkage gaps are filled.

There are many variations on this. An interesting one is a framework of vertical wooden columns and thin wooden members as a triangular infill. The space between this wooden structure is filled with stones and mud. This was widely used in Northern Pakistan.

In Afghanistan, one of the historical school buildings has a mixed wall construction, where

Building Construction, Fig. 2 Wattle and daub wall in an old German house, now used for exhibitions (Photo by the author)

Building Construction, Fig. 3 School building in rammed earth in Kabul, Afghanistan (Photo by the author)

the faces of the walls are made of mud bricks and the core of the walls is filled with rammed earth. Corners are made of burnt bricks in mud mortar. This two-story building in the center of Kabul is more than 100 years old, and the walls are still sound (Figs. 3, 4, and 5).

More about mud technologies (as well as their further development with lime or cement

stabilizers) can be found in Doat and Norton (1991), Minke (1999), and Niemeyer (1946).

5. Typical for many tropical hot and humid areas (where day and night temperatures vary only slightly) are light and easily ventilating walls. There the users can benefit from the slightest breeze. These walls are mostly made entirely

Building Construction, Fig. 4 Old castle near Kabul, Afghanistan (with rammed earth) (Photo by the author)

Building Construction, Fig. 5 Detail of the rammed earth blocks (Photo by the author)

of bamboo, but one can also find grass or palm leaves as cladding. Even entire structures of strong grasslike reed existed where this grows close to swampy areas, for example, in the marshes (North of Basra) in Iraq (Thesinger, 1967). They are bound together as in Thor Heyerdahl's famous boat Ra and can form quite sizable arch structures (Fig. 6).

6. A structurally interesting system concerns Chinese temples and other important

historical buildings, where wooden columns (with infill or free standing) carry the roof. Such freestanding columns get their horizontal stiffness against wind mainly due to a high load from the roof. The horizontal load from the wind is related to the height of the structure, and adding vertical loads can increase the horizontal resistance. This is exactly the case, as the tiles of these Chinese roofs are embedded in a thick layer of special mortar. From

Building Construction,
Fig. 6 Thor Heyerdahl's
 boat (exhibition in
 Tenerife, Spain). Similar
 technology is used in the
 swamps of Iraq for
 buildings (Photo by the
 author)

Building Construction,
Fig. 7 Roof structure
 (Dubai) beams, mats, and
 mud as topping (Photo by
 the author)

below it looks like a full wooden roof. Leaving the mortar out would seriously harm the structural integrity. Unfortunately this strategy does not work in the case of earthquakes, as there the horizontal forces are related to the mass. So adding more weight in the roof does not help; old pagodas collapsed during earthquakes.

Slabs

Slabs and flat roofs are normally supported by wooden beams with different infill materials. The major ones are:

1. Stones, which are then covered with mortar or mud. In this case, the beams have to be rather close together. Larger crossbeams can often support small secondary beams. This construction is rather typical for the east African coast with its Arabic influence.
2. Mud, reinforced by wooden branches. The construction usually starts with a mat (bamboo or similar), which prevents the mud from falling down. The branches, being fully embedded in the mud, act as a reinforcement, so that the distance between the beams can be larger up to about 45–60 cm (1.5–2 ft) (Fig. 7).

Building Construction,
Fig. 8 Support of a roof in
 China (Photo by the author)

B

3. In Rajasthan, India, ceilings and roofs are made in stone-producing regions by placing a stronger stone as a beam and stone plates between those beams.

Roof Structures

In addition to slab roofs, one can find the following basic roof structures:

1. Wooden beam structures, where besides, the purlin (A purlin or purline is a piece of timber laid horizontally on the principal roof frames support the roofing material. Another design is with common rafters on which the roof covering (then usually tiles) is laid mostly using battens. Those rafters are supported by roof beams and used in inclined roofs and are parallel to the gable) and rafter construction, we can mention some interesting other types. (1) In traditional Chinese roofs, the main load-bearing element consists of wooden beams arranged one on top of the other with small spaces in between. The top beams get shorter to follow the form of the gable. This makes larger spans possible without doing complicated latticework, although at the expense of more timber consumption (Fig. 8). (2) Some communities in Gujarat, India, built conical roofs with small beams without intermediate support, which act like shells (see case study). Others build a wooden dome on a square house using strong branches

Building Construction, Fig. 9 Simple *bungha* roof from the inside (Photo by the author)

(Figs. 9 and 10). (3) In Eastern Africa large roofs were built using tree-type support systems. Now one can find this efficient system being revived in beach resorts at the Mombassa coast (Fig. 11).

 structure out of branches
 (Gujarat, India) (Photo by
 the author)

Building Construction,
Fig. 11 Roof structure
 with tree-type supports
 (beach resort in Kenya)
 (Photo by the author)

2. Domes and vaults are often used in desert architecture. Most are made of mud bricks, as they have sufficient strength. The main problem in a dome and vault construction is to counterbalance the horizontal thrust. Heavy and sometimes inclined walls do this. If stones are used for domes, a good overlapping can take a lot of the horizontal tension. This is the case in many old mosques and temples (Fig. 12). Tension belts, which would be the

best technical and scientific response to the problem, are not used to my knowledge. For vaults, only horizontal tension beams lead to an improvement. They can be found, for example, in old Ottoman buildings in the Balkans, where wooden beams carry an intermediate floor under the vault. Removing such a floor with its beams could lead to collapse; even a replacement not respecting the invisible anchoring detail could have this effect.

Building Construction,
Fig. 12 Dome (Jumma
 Mosque, Ahmedabad).
 Ring forces balanced by
 overlapping; joints open
 where there is a little
 overlapping (Photo by the
 author)

B

Interesting information on how to build domes and vaults without shuttering can be found in Doat and Norton (1991) and Minke (1999).

The above example as well as the Chinese roof (that stabilizes the wall columns by its weight) demonstrates how dangerous it could be to change traditional construction. One has either to follow the tradition strictly or one must fully understand how it works.

Roofing Material

Roofing material for waterproofing varies a lot.

1. Slab roofs (which are prevalent in dry climates) have mud layers for waterproofing. In some cases they are covered with an additional layer of bricks or clay floor tiles laid to slope. This makes their use as roof terraces more convenient. Normally they are only a mixture of mud and chaff. This cover is in some rare cases also used for sloped roofs.
2. Suitable leaves or grasses are very common covers for sloped roofs. There is the well-known thatch roof using various types of local grasses, some of them are more and some are less resistant. Palm branches are prepared by folding them in half, so that the stalk is one side and the whole piece can be bound to the substructure. This type of roof is called *macuti* in Eastern Africa. The pieces are laid with overlapping shingles. Rounder growing palm leaves are simply overlapped. All these roofs provide good ventilation and heat insulation which make the houses comfortable. However every 3 years or so, thatch type roofing needs to be replaced, which is costly for the owners, and good material gets scarce in some regions.
3. Burnt clay tiles were common in some areas of India and for all official buildings in China, where they are normally glazed. As mentioned, in China, tiles are laid on top of a wooden structure in mortar. In India traditional country tiles were made of short conical pipes that were cut into halves. They are like all traditional tiles laid one on the bottom as a channel and one on top to cover the gap between the two bottom tiles. A more recent type has a U-section as a tapered channel and is laid in the same manner. People who could afford put several layers on the roof for better heat protection. The small gaps in such tiled roofs ensure good ventilation. Predominantly a layer of split bamboo supports the tiles. It is safer than the one batten per tile as we know it. In case an earthquake or high wind moves the tiles, they cannot fall down and cause harm. In some regions of India, one can also find such tiles laid in mud on simple thatched roofs (Figs. 13 and 14).
4. Domes and vaults get a finishing by lime plaster. To make this watertight, the sand used must have different grains and some organic

Building Construction,

 (Gujarat, India). Split
 bamboo placed close
 together serves as battens
 (Photo by the author)

Building Construction,
Fig. 14 Country tile roof
 from inside (Photo by the
 author)

material added in order to increase the elasticity.

5. Regions with suitable stone plates have sloped roofs with overlapping stone slabs (Fig. 15).

Earthquake Resistance

In many non-Western regions, earthquakes are a major natural hazard, and all buildings are built to resist their forces.

It is not the earthquake that kills; it is the collapsing building. Traditional constructions have a remarkable earthquake resistance. Problems start when the traditional way of construction is modified. Craftspeople who execute the

works cannot really design for earthquake resistance once traditional design is given up. The strength and the proper dimension of a structure were developed by experience, and this is also reflected in the features that may make a structure more earthquake resistant, even if they are not recognized as structural elements. Even builders might not know why there are certain elements, which users normally consider decoration, which often play a vital role in the buildings' strength.

An earthquake's actions can in a simplified way be understood as horizontal forces acting on the structure. They are more or less proportional to the mass of the structure concerned and are expressed as percentage of the gravity acceleration.

Building Construction,

Fig. 15 Roof with a stone slab (Rajasthan, India)
(Photo by the author)

B

Various strategies deal with earthquake safety. Basically one can have (a) buildings that do not harm people when they collapse; (b) a construction that is light where earthquakes do not induce large forces; and (c) buildings can be strengthened in various ways to withstand earthquakes. Often a combination of those measures is used. One can also have a rather elastic and flexible structure, which reacts by deformation, but that is not the case in traditional buildings.

Traditional Japanese houses consist only of a light wooden structure and a sort of paper filling for the walls. As the structure is light, an earthquake will not introduce many forces, and if it collapses, the walls are not seriously hurting users. This is an intelligent construction using strategies (a) and (b).

All types of thatched roofs (real thatch and covers from palm or banana leaves) always supported by a wooden structure follow the same strategy. They are light and will not cause harm when the roof collapses. Even roof tiles did not result in serious injuries when falling down during earthquakes (or cyclones). As mentioned, in India, there were many pieces of split bamboo lying so close together that tiles could not fall through. However, when modern roof tiles were introduced, this feature was given up, as those new tiles only match well with single straight battens as support. Central Europe, where the design of modern tiles comes from, has not got serious earthquake problems, and there is always

a ceiling under the roof. Introducing the same technology in earthquake-prone areas like northern India, where people normally cannot afford a cladding under the roof, was probably not a good idea. In the great Gujarat earthquake in 2001, falling tiles injured people, but practically nobody was killed. The death toll came mainly from collapsing slabs or slab roofs, especially when their supports failed.

To make the building itself resistant to prevailing earthquakes, following strategy (c) can be achieved in various ways. Rather resistant are wooden structures, filled with either woven mats or similar (which is the usual construction in the real tropics (see section “[Climatic Adaptation](#)”)) or with mud (mostly a wattle and daub type, see wall materials). Some latticework or diagonals increase the horizontal resistance. However, often the traditional joints are a weak point.

You often find this type of approach for the first floor of two-story houses. It has a long tradition in Muslim construction and can still be seen in old Turkish towns as well as in Kabul, Afghanistan. The first floor weight is more essential to the structure, as it contributes more to the internal forces, so it is wise to make it light.

A good way to reinforce masonry buildings against earthquake actions is to use horizontal bands with good tension strength. This is the recommended method for one- and two-story buildings in many modern earthquake-related

building design standards. Today, the bands are normally made of reinforced concrete. You will find similar bands in Turkey and in the Himalayan region of India, etc., where houses are constructed of stones. These bands are however made of wood, a material that is relatively cheap and has good tension strength. There you find one piece of wood on either side of the wall, often interconnected in a form of a ladder by smaller batten type pieces. It looks and acts very similar to modern steel reinforcement in concrete beams. In the Himalayan region, people most likely discovered independently from the Arabic-influenced regions the positive effect of wooden beams in case of earthquakes. You can find buildings, mainly with dry masonry, which have wooden beams incorporated. They look very nice and can be considered as traditional decoration, but basically, they are reinforced against earthquakes.

Wattle and daub walls have also a rather high-tension strength, as the basic structure consists of wood. In addition, the walls are light and do not attract high horizontal forces.

Another way to increase the strength of a structure is to give it a suitable form. If you fold a piece of paper, the load bearing capacity becomes much greater compared to a flat piece. Round forms are very resistant, and this is used in certain types of buildings. In Gujarat, India, such a house type, called *bungha*, withstood the last heavy earthquake amazingly well (see the case study below).

A very simple and basic approach to make a wall itself earthquake resistant is to make it thicker. Assuming that the wall is sufficiently monolithic, one can assume that the resultant of the horizontal earthquake forces acts in the center of gravity of the wall, for a prismatic object that is the middle of the height. If the wall is wide enough in relation to the height, it cannot turn over. This is why huts (with light thatched roofs) and low stonewalls have no problems in earthquakes, even if they are only built with mud mortar. More effective are tapered walls with a wide base in the form of a retention wall or dam. This approach can still be found in earthquake-prone areas (Fig. 16).

Building Construction, Fig. 16 Mud wall in a tapered form to withstand horizontal earthquake forces (Gujarat, India) (Photo by the author)

In general, as one could see, traditional buildings were amazingly well adapted to earthquake hazards and this within a rather limited range of available local materials. Many problems started, when traditions were given up and westernized construction was imitated without designing the buildings for the prevalent hazards.

Climatic Adaptation

For a good adaptation to the climate, the construction of a house plays a major role. Together with the architecture (Koenigsberger et al., 1973; Lippsmeier, 1969; Wilhelm 2000), which should deal with orientation, shadowing, openings, and spatial arrangements, the temperature and the air movement and the type of material used and its dimension also influence major components of comfort.

In desert conditions, thick and heavy walls provide a good phasing (time shifting of the temperature curve between outside and inside the

building) and damping of the temperature. Mud and rubble stonewalls in the range of 30–45 cm (1–1.5 ft) as used in traditional constructions in such regions have a phasing of 12 h or so. This is how people can benefit from cool nights during the daytime. In the night they sleep outside or ventilate the room, if it is too hot from the heat stored during the day. A straw rich mud plaster normally increases the insulation and contributes to the damping effect. So the peak temperatures inside are lower than outside and closer to the average. In the desert environment, the rooms stay within comfortable conditions, whereas a prefabricated concrete building with thin elements as required for structural safety becomes too hot (Fathy, 1986).

In tropical conditions, light walls are traditional, which makes it possible to benefit from the slightest change of temperature. Weavings also let the air through, so that the users get more comfort through the air movement. All traditional houses in hot climates have openings near the roof or a roof that let the air pass through. In thatched or palm leaf roof covers, this advantage is combined with good insulation properties so that the heat is kept out.

Ventilation can be further increased, if the floor is penetrable and put on stilts. Houses on the Southeast Asian islands with bamboo floors follow this strategy. A further improvement of the ventilation can come through a chimney effect. Raised gables in Bali, chimney-type additions on the center of the roof, wind towers in Arabia, and holes on the top of domes are such devices (Fig. 17).

Example 1: Traditional Bungahas in the Semidesert of Kutch, Gujarat, and India

Probably the oldest types of houses in the semidesert of Kutch are called *bungahas*. They look very much like the well-known African round huts. They were considered rather backward and primitive type of construction. The big surprise was their amazingly good performance during the high-magnitude earthquake in January 2001, where nearly 20,000 people died in the region.

Practically none of these buildings collapsed, except for those that were rotten, as the wooden

Building Construction, Fig. 17 Wind catcher tower (Dubai) (Photo by the author)

roof structure and the walls had been weakened by termite attacks. Looking closer into the quality of the bungahas, one finds a very good adaptation to the desert climate with hot days and cool nights.

The bungahas are round structures, standing on platforms for better protection from the rain, which weakens the mud walls, as there are heavy rains from time to time. Several bungahas are placed together on this platform, forming the home of a large family. The houses with mud plaster are often nicely decorated and have furniture made of fiber-reinforced mud with a lot of decorations. The walls are in many cases made of wet mud pieces put in layers. In some cases sun-dried mud bricks are used, fixed together with mud mortar (Figs. 18 and 19).

Another wall type consists of random rubble stone masonry, again fixed together with mud mortar. The fourth wall type found in some areas is the wattle and daub construction.

The wall thickness varies with the material. Wattle and daub is normally about 15 cm. This is

Building Construction,

Fig. 18 Decorated *bungha*
(Gujarat, India) (Photo by
the author)

Building Construction, Fig. 19 Grain storage made of fiber-reinforced mud (Kutch, Gujarat, India) (Photo by the author)

the thickness that results from the material used, and it is rather appropriate to provide a reasonable insulation and damping to cope with the high temperature differences between days and nights.

The filling with branches, together with the mud layers on both sides, has rather good thermal properties. However from the point of view of building physics, a slightly thicker wall would be desirable.

The pure mud walls are about 30 cm thick, which ideally corresponds to the damping and insulation requirements. Mud mortar rubble stonewalls are generally 45 cm or 1.5 ft, which again corresponds ideally to the thermal requirements. The round form gives the walls a great stability, which explains the good performance of the bungha during the earthquake. The conical roofs are made of wooden rafters and covered with thatch. To interconnect the rafters, small branches or the core of palm leaves are used in small bunches that can easily be bent into horizontal rings. From the top, such a roof structure looks like a spider's web: the rafters go in a radial form from the center to the wall, and their interconnections form concentric rings.

Many communities use a king post in the center of the room. They put a heavy beam on top of the wall about 1.80 m high, on which the king post ends. These people are sure that the king post is necessary, but other communities manage without it. They use a corner piece for each rafter to transmit the horizontal thrust of the conical roof to the walls that are acting as a tension ring. This interesting innovation takes

longer to spread to the other communities living in the same region where bungalhas are built (Figs. 20 and 21).

The roof cover is made of thatch, which has good insulation properties and at the same time lets air pass through and provides a good insulation for the buildings. Together with the good

insulation and storage capacity of the walls, the house is kept cool during the day, and it is also comfortable in the cold nights in winter, which can reach zero degrees. Users are well aware of this, and they call it a built-in air-conditioning system. However they would like some improvements like better flooring and longer lasting roof materials.

Building Construction, Fig. 20 Old *bungha* roof (Kutch, Gujarat, India). Large roof without king post and excellent decoration (Photo by the author)

Building Construction, Fig. 21 Detail: corner element in a *bungha* roof (Photo by the author)

Example 2: The Afghan City House

Afghanistan has a harsh climate (hot summers, relatively cold winters and nights), and in addition there are earthquake hazards. Traditional housing is well adapted to those conditions. Whereas in villages, single story mud or stone houses are prevalent, and cities like Kabul have a long tradition of two-story buildings.

The plinth is built in random rubble stone dry masonry. This keeps the moisture from the soil out of the walls. In western technology the damp proof courses were only introduced in the beginning of the last century, normally as bitumen felt layers.

The ground flooring is laid on top of the so-called fox's dens. This is a system of ducts, which ventilate the space under the floor, and is in some cases used as a heating system similar to the Roman hypocausts (hollow floors and in some cases wall ducts, where fire was made for heating). Transverse main ducts connect both exterior plinth walls, so that the air can pass through. From this main duct secondary ducts run in a perpendicular direction. Then a layer of mud follows which

carries the flooring, which is either made of brick or only mud. This construction keeps the floor dry. The ground floor walls are made of sun-dried mud bricks with a wall thickness of at least 30 cm (12 in.).

This corresponds ideally to the climatic requirements, as this wall has a high storage capacity and a phasing of up to 12 h. This room is cool on summer days (as it preserves the night temperature condition). A wooden framework with an infill of sun-dried mud bricks forms the upper floor walls. These upper walls are only about 12 cm (5 in.) thick and have large windows. So the rooms in the upper floors pick up the outside conditions much faster, and one can choose the most comfortable room. The light walls, together with the wooden framework and a sort of batten as bracing against horizontal forces, make the building rather earthquake resistant.

The floor and the roof slab have wooden beams as load-bearing structures at 45–60 cm apart (1.5–2 ft). As described earlier, there is a reinforced mud layer across the beams. To get the roof watertight, a layer of mud mixed with hacked straw is applied, which needs to be replaced every few years.

Some houses of this type are reported to be 200 years old, and the technology is still used today. Those and more modern examples show the potential of mud houses.

Improving the traditional construction systems would be a real benefit for the poor, who mostly have only their labor to invest.

Building Construction in Africa: Akan

Tarikhu Farrar

The indigenous timber and clay building technology of the Akan peoples of southern Ghana is a later expression of an ancient tradition of timber frame construction. Timber frame building had attained a considerable level of sophistication and beauty by the early nineteenth century as evidenced in the architecture of the Asante kingdom, and especially that of its capital, Kumasi. Such sophistication, in light of the antiquity of timber frame building in the region, should not be surprising. Nor should we be at a loss to account for its origins.

Akan coursed clay construction is less well known than timber frame construction. It was not as widely practiced as timber frame construction in pre-colonial times, particularly in the regions of dense forest. It seems to have been more common in the region occupied by the Northern Akan, the Bono (or Brong), and in parts of the central coastal plain occupied by the Fanti. The product of this type of building is a structure consisting of freestanding, solid clay walls. Coursed clay construction in the Bono region dates to at

least as early as the beginning of the second millennium CE, and perhaps much earlier. See more on this below.

Earlier generations of archaeologists, ancient historians, and architectural historians tended to denigrate or ignore this and similar types of architecture. In the first place, these building traditions did not employ “respectable” building materials (e.g., stone), and, moreover, little evidence could be found of what they considered to be “monumental” architecture. Implicit was the idea that the dwellings, and work and storage structures utilized by non-elite people, was not worthy of serious study.

The architectural traditions of much of Africa, and virtually all of tropical/sub-Saharan, or Black Africa, were not thought to be worthy of serious study; even the designation “architecture” was not assigned. “Huts,” “mud huts,” “thatch huts,” “wattle and daub huts,” etc., were used instead. If the term architecture was used at all, it was qualified. Thus reference was made to “mud architecture,” “wattle and daub architecture,” or more generically, “primitive architecture.” As for “true” architecture, the prerequisite was that it usually had to be effected in stone. If clay architecture were to be considered at all, the clay had to be formed into units of regular size and shape, and kiln-fired. If these two requisites were met, one could refer to “brick,” “red brick,” or “fired brick,” and this type of brick was respectable enough. Clay formed into units of regular size and shape, but not fired, was “mud brick,” and less worthy of serious study.

When African history emerged as a discipline in the second half of the twentieth century, at a time that, not coincidentally, corresponds to era of the struggles for African independence, and the anti-colonial struggles of the “third world” more generally, a growing number of scholars began to pay serious attention to what they termed “African traditional architecture.” Their pioneering research and writing has resulted in a respectable and expanding literature on this subject. Although too much of the old terminology has been slow in changing (we still read of “mud” architecture, for example), a serious, scholarly study of indigenous African architecture has

unfolded which has effectively challenged the older, entrenched stereotypes. Most of this research has focused on the products of the building process rather than the building process itself. In this entry, however, consideration will be given to the latter. (See author’s “Building Technology” entry in the encyclopaedia.)

Timber Frame Building Construction

The Akan peoples of southern Ghana and adjacent parts of Cote d’Ivoire possess two indigenous timber frame architectural forms. One, the *mpapa-dan* structure, is built entirely of plant materials. The other, the *tare-dan* structure, consists of a timber framework with an infilling and final plaster of clay. The former is normally a short-term dwelling, while the latter is expected to have much greater longevity.

Timber frame building construction in southern Ghana is of considerable antiquity. Its antecedents go back to the mid-second millennium BCE. or earlier. It has been firmly associated with the region’s earliest food producing communities of the Kintampo Culture. (For example, see Anquandah, 1976a, p. 92, 1976b, pp. 33–35, 1982, pp. 55–65, 1993, pp. 255–260; Davies, 1967, pp. 115–118; Dombrowski, 1976, pp. 64–71, 1980, pp. 261–262.) The architectural remains associated with the Kintampo Culture are the oldest yet uncovered in West Africa south of the Senegal River, and represent the oldest known timber frame building tradition in tropical Africa outside of the Sudanese Nile valley.

Although mention is made of local architecture in the writings of European mariners dating to as early as the mid-sixteenth century (for example, see Towerson ca. 1555–1557, in Blake, 1942, p. 406), relatively good written documentation of timber frame building for coastal Ghana, known then as the Gold Coast, dates from the mid-seventeenth century. Jean Barbot, resident on the coast from 1678 to 1682, describes one of the local timber building methods:

The *Blacks* generally build their houses on four posts or trunks of trees, drove into the ground, at such a distance as they design the largeness of the

house to be, and about six or seven foot high, to those main corners of the houses they fasten three or four poles athwart at equal distances above one another, and again others across them downwards, from the uppermost to the ground. The houses being thus framed, they lay on a sort of clay or plastering both within and without, about eight inches in thickness; which in a very short time, by the heat of the sun, becomes almost as hard and solid as a stone wall, leaving a few small lights or holes in the wall, and a very low and narrow door, or passage, to go in or out at. Lastly, they for the most part colour the inside of the wall, white and red, or black and yellow, as everyone likes best.

On those mud and timber walls they lay small quarters across both ways for the roof; and instead of tiles, cover them with palm tree, or rice leaves, or bulrushes, as the place they live in affords. In most houses the roof is so contrived, that it opens at the top, to let in air, when the weather is hot.

The ground floor of the house is of the same sort of hard clay, as the walls, and in the midst of it is a hole to hold a pot of palm-wine, when they meet to make merry. (Barbot, 1732, pp. 252–254)

The type of timber framing that Barbot describes is, in fact, one of several types that were practiced locally. A second type, for example, utilized posts and studs. Both posts and studs were planted into the ground, and to these vertical timber elements, the horizontal ones, or laths, were attached. Laths were extended both on the inside and outside of the posts and studs. Posts and studs, and especially posts, were more massive and functioned as structural elements in the building. This was also true of kingposts, ridge-beam, wall plates, eaves supports, and end-girts, and of ceiling girts if used. All of the more massive, structural timber elements were ideally decay and insect resistant hardwood. For posts, studs and ridge-beams this was essential. Akan builders relied on a number of tree species known for their resistance to insects and decay.

By contrast, laths, rafters and thatch-poles were slighter timbers, laths being slightest of all. Often these elements consisted of the midrib of the raphia palm (*ntuntun*, in Twi-Fanti), or that of the oil palm (*mpapa*). In the coastal region, ► **bamboo** was used for these lighter elements of the framework, particularly for laths. In the northern Akan or Bono region, *babadua* was used much in the same way as bamboo in the

coastal region. *Babadua*, when stripped of its foliage resembles bamboo, and is easily mistaken for such.

Barbot mentions different plant materials used for thatching. He also describes how thatch is first attached to a framework – what today Fanti builders call a “roofing sheet” – and how the roofing sheet is then attached to the thatch-poles of the roof framework. In fact, the way that roofing sheets were prepared had everything to do with the material used. Use of palm leaves, and the type of palm leaves used, was characterized by one set of methods. (The coastal Fanti used coconut and raphia palm leaves, while the Asante and other peoples of the dense forest used raphia and oil palm leaves.) Grasses and shrub leaves (these were more common in the Bono region), and, again, several types were used, required a different set of methods. The Fanti even manufactured a kind of “tile” for roofing purposes from bamboo. Stalks of bamboo of considerable girth were split in two lengthwise, and tile-like pieces were cut from these.

In no part of the Akan region did timber frame construction reach a greater degree of sophistication than in the Asante region during the time of Asante ascendancy. Thomas Bowditch, science officer of the first official British mission to Kumasi, the Asante capital, has provided us with a fascinating glimpse, through word and illustration, of Asante architecture at its best in the early nineteenth century. Bowditch’s description of the building of the large, elegant “town houses,” as he dubbed them, of Kumasi is invaluable:

In building a house, a mould was made for receiving the swish of clay, by two rows of stakes and wattle work, placed at a distance equal to the intended thickness of the wall; as two mud walls were raised at convenient distances, to receive the plum pudding stone which formed the walls of the vitrified fortress in Scotland. The interval was then filled up with a gravelly clay, mixed with water, with which the outward surface of the frame or stake work was also thickly plastered, so as to impose the appearance of an entire thick mud wall. The houses had all gable ends, and three thick poles were joined to each; one from the highest point, forming the ridge of the roof, and one on each side, from the base of the triangular

part of the gable; these supported a frame work of bamboo, over which an interwoven thatch of palm leaves was laid, and tied with the runners of trees, first to the large poles running from gable to gable, and afterwards, (within,) the interlacing of the bamboo frame work, which was painted black and polished, so as to look much better than any rude ceiling would, of which they have no idea. . . The pillars, which assist to support the roof, and form the proscenium or open front (which none but the captains are allowed to have to their houses) were thick poles afterwards squared with a plastering of swish. The steps and raised floor of these rooms were clay and stone, with a thick layer of red earth, which abounds in the neighbourhood, and these were washed and painted daily, with an infusion of the same earth in water. . .

A white wash, very frequently renewed, was made from a clay in the neighbourhood. . . The doors were an entire piece of cotton wood, cut with great labour out of the stems or buttress of that tree. . . Where they raised a first floor, the under room was divided into two by an intersecting wall, to support the rafters for the upper room, which were generally covered with a frame work thickly plastered over with red ochre. . . (Bowditch, 1966 [1819], pp. 304–306)

This was Akan timber and clay construction *par excellence*. It was the legacy of more than three millennia of timber and clay building in southern Ghana. As with Barbot's description, we are again exposed to but one of several different forms of timber and clay construction practiced in the region, in this case that which produced the houses of the Asante aristocracy, and the architecture of the kingdom's major political centers.

Aside from size and degree and complexity of surface decoration, the most common type of Asante non-aristocratic dwelling would not have differed greatly from those of the aristocracy. With some differences having to do with the much smaller size of ordinary Asante dwellings, wooden framework construction paralleled that described for Asante "town houses." The most divergent type of timber frame construction involved the building of an *mpapa-dan* structure. But even here, differences were not terribly great. In fact, the most significant difference (besides its smaller size) was the absence of studs and the many fewer laths of an *mpapa-dan* timber framework. (For a more detailed description of the

various types and methods of timber frame construction, see Farrar, 1996, pp. 95–151.)

In the far north of the Akan region, among the Bono, local variants of timber frame construction evolved, still part of a broader Akan building tradition, but rooted in local environmental conditions. In the Bono region, however, building in coursed clay was far more common in pre-colonial times than farther south. Archaeology tells us that for the Bono, this tradition goes back for at least a millennium.

Akan Coursed Clay Construction: Some Brief Observations

Despite the fact that the Bono peoples have built in coursed clay for a 1,000 years or more, the Akan peoples in general have not been the most prolific builders in this medium. Their skills in coursed clay construction have certainly been adequate, but their neighbours to the north, east and southeast of them have historically been more adept at it. Some question surrounds the antiquity of coursed clay building in Ghana. The writer has argued elsewhere (Farrar, 1996, pp. 156–168) that coursed clay construction in Ghana may also (that is, along with timber frame construction) date to as early as the Kintampo Culture, as evidenced by the remains of associated structures with stone foundations. Timber frame construction in this part of Africa *never* employs stone foundations, and, as far as we know, never has. Moreover, stone foundations would interfere with the placing of posts and studs, and would do nothing to enhance the strength or longevity of the walls. Some forms of coursed clay construction, on the other hand, do employ stone foundations. Akan builders do not lay stone foundations when building in coursed clay, but neighbouring peoples in southern Ghana (e.g. the Ga and Dangme) do.

There is, perhaps, a tendency to think of coursed clay building as a more complex form of building technology than timber frame construction. But this is not necessarily so. We need only remember that the earliest village agriculturalists of Upper Egypt, the Badarians, built

Building Construction in Africa: Akan, Fig. 1 The great court of the Asantehene's palace (Kumasi From Dupuis, 1824), frontispiece

dwelling with solid clay walls. Thus, we should not fall into the trap of dismissing the possibility that coursed clay construction was practiced in West Africa – in Ghana – by local, early food producing communities of 3,500 years ago, on the basis of the dubious assumption that it is too “advanced.” This type of thinking about coursed clay construction is, perhaps, the basis of the suggestion that it must have come later, as an introduction or borrowing from more “advanced” cultures.

Coursed clay construction is related technologically to the building methods known in other parts of the world as *pise*, *tapia*, rammed earth and *tauf*. The product of this method of building is a structure with freestanding, solid clay walls. To achieve this end, certain requirements must be met with respect to the building material that is used, and how it is used. For Akan builders, *ntwuma*, a local, deep red, light clay with high iron content, is the most preferred for the raising of walls. But any earth with a good light to medium clay content can be used. If the clay content is poor, the walls will crack and crumble upon drying. Furthermore, the clay must be of the proper sand-to-clay ratio. If such clay cannot not

be found in the immediate vicinity of construction by digging far enough below the surface, it must be quarried from elsewhere and brought to the building site. (The same clays, by the way, are used for wall infilling in timber and clay construction, and they are prepared in the exact same manner.)

Clay is prepared by adding water and the mixture is “trodden.” Balls of clay are formed that are about the size of a human head, and these are thrown or rammed into place. Walls are raised in layers, or courses, and each course of the wall is more or less the same height, ca. 50–60 cm. However, each successive course is slightly thinner than the previous one. Thus, the first course, that which constitutes the base of the wall, has an average thickness of 30–45 cm. The final, or top, course averages 20–30 cm in thickness.

Builders explain that the practice of gradually thinning the wall with height is based on a simple structural principle: each successive course must be lighter than the previous one or the latter will crack and possibly crumble under the weight of the former. The same principle is echoed by Se Dangme and Anlo Ewe builders (the writer studied coursed clay building practiced by both

Building Construction in Africa: Akan, Fig. 2 The architecture of early nineteenth century Kumasi, the Asante Capital

Building Construction in Africa: Akan, Fig. 3 Kumasi “town houses” (as Bowditch called them). Dwelling of Kumasi’s political elite

groups), although their method of decreasing the weight of successive wall courses involves reducing the height of each course.

Each wall course must be allowed to dry sufficiently before the next is added. The amount of time for drying obviously varies depending on the season, but at least a week is necessary. If a course has not dried sufficiently, it will crumble under the weight of the addition. The coordinate courses of each of the four walls rise simultaneously as if the shell of the building were “growing” out of the ground. Spaces for doors and windows are left during wall construction as opposed to being cut in later, as is the case in

some coursed clay building traditions. The framework for the roof is constructed entirely of timber, and consists of all of the same timber elements that a roof in a timber frame house has.

This description of coursed clay wall construction comes entirely from ethnoarchaeological research. We have no written accounts of the construction of coursed clay buildings in southern Ghana for the time span extending from the early contact to the later pre-colonial periods, as is the case for timber frame construction. What we know from archaeology, however, is that Northern Akan peoples, the Bono, practiced coursed clay construction in their settlements a

Building Construction in Africa: Akan,

Fig. 4 Elements of Akan timber framework construction

1,000 years ago. Most notable of these settlements, and one that has experienced some archaeological investigation, is the site of the early Akan city of Bono Manso (see, for example, Effah-Gyamfi 1975, 1978, 1979, pp. 173–186). Ethnoarchaeological studies may shed considerable light on the building technology that was practiced at early Akan settlements, so long ago.

In pre-colonial times, impressive structures of timber and clay, large elegant, adorned with beautiful surface decoration, and some of them two storeys high, characterized the major Akan settlements. The best known of these are the Asante “town houses,” so carefully and respectfully described by Thomas Bowditch in the early nineteenth century. In the north of the Akan region, the Bono, too, had their aristocratic town dwellings, but as early as the beginning of the second

millennium CE, these structures were as likely, perhaps more so, to be constructed in coursed clay. Ordinary people throughout the Akan world lived in smaller, less ornate versions of timber and clay and coursed clay dwellings. But the descriptions that we have of these dwellings, mainly from early to mid-nineteenth century sources for the interior, suggest that they were not lacking in beauty, comfort, and durability.

Well before the mid-twentieth century, the larger, two-storeyed timber and clay dwellings were no longer being built. Before century’s end, the practical knowledge of how to build them had disappeared. In the Bono region, large structures of coursed clay continued to be built, but the largest of buildings, now multi-storeyed, were more likely to be constructed in brick, “English style” brick, or *mrikes*, as they are locally called.

Building Construction in Africa: Akan, Fig. 5 The great court of the Asantehene's palace (Kumasi From Dupuis, 1824), frontispiece

Indigenous Akan building construction is still practiced, primarily in rural areas, but it is, seemingly, on the road to extinction. Indigenous architecture, no matter how attractive or well built, carries no prestige. It is thought to be backward, inconsistent with modernity, and thus, undesirable. Extinction may be the destiny for all systems of traditional architecture and building technology. Whether or not this is for the better is a subject for debate. One thing, perhaps, is not so debatable: valuable knowledge can be gained by those who would design and build tropical Africa's architecture of the future, from the study of the architecture and building technology of those who built it in the past (Figs. 1, 2, 3, 4, and 5).

Cakravala Method

S. Raghavan

Adyar, Chennai, India

Let us consider the equations (i) $3x = 6$ and (ii) $5y = 2$ in the two variables x, y . We recognize at once the (integer) solution $x = 2$ for equation (i) and further note that there can be no y in the set $\mathbf{N} := \{1, 2, 3, \dots\}$ of natural numbers which satisfies equation (ii), since the constant term 2 on the right-hand side of equation (ii) is not an integral *multiple* of (i.e., is not divisible by) the coefficient 5 of the variable y therein. Leaving these two simple examples of linear equations in a single variable, let us take up the following linear equation involving two variables x and y :

$$px - qy = m \quad (1)$$

where the coefficients p, q and the constant term m belong to the ring $\mathbf{Z}$ of the usual integers. $\dots -3, -2, -1, 0, 1, 2, 3, \dots$. Clearly, for (Eq. 1) to have a solution $x = a, y = b$ with a, b in $\mathbf{Z}$, it is necessary that any common divisor t of p and q (i.e. any t in $\mathbf{Z}$ dividing both p and q) must be a divisor of m as well. Thus the greatest common divisor (g.c.d. in brief) d of p and q denoted as (p, q) in symbols must also divide m . Now, a well-known algorithm of Euclid's for finding (in finitely many steps) the g.c.d. of any two given integers p, q enables us to write

their g.c.d. d in the form $d = pa + qb$ with suitable a, b in $\mathbf{Z}$, and we are led to the solution for (Eq. 1) in integers $x = am/d, y = -bm/d$. We should not fail to mention that an alternative approach to solving (Eq. 1) is to expand the rational number q/p (for $p \neq 0$) as a simple continued fraction. For example, if $p = 3, q = 11$ in (Eq. 1), then $q/p = 11/3$ has the continued fraction expansion $(3 + 1)/1 + 1/2$ whose "penultimate convergent" $(3 + 1)/(1 + 4/1)$ solves this special case of (Eq. 1) with $x = 4, y = 1$.

Solving linear equations such as (Eq. 1) in two variables or in more variables often opens the door to cracking interesting puzzles or even settling serious problems! A clear description of the method of solving (Eq. 1) is available in *Āryabhaṭīya*, a Sanskrit text of the (fifth or) sixth century AD. (According to Ian Pearce (2002), the mathematical part of *Āryabhaṭīya* covers arithmetic, algebra, plane trigonometry and spherical trigonometry and also contains continued fractions.) As observed by André Weil, this is also "the first ever explicit description" of the general solution in integers for (Eq. 1) from anywhere, except China. In subsequent Sanskrit treatises, this method came to be known as the *kuttaka* (pulveriser) method, but it might not be fair to attribute the same with authority to Greek mathematicians granting the familiarity of Indian astronomers with developments in Greek mathematics until then. It is interesting to learn from Weil how, in utter disregard or (possible) ignorance of the remarkable application of the *kuttaka*

in India and of the connection with the seventh book of Euclid's *Elementa*, Bachet ventured to insert (in the second edition of his book *Problèmes plaisants et délectables*) a strong claim to the *kuttaka* method as his own. Before attempting to say anything about the *cakravāla* method, let us see how the *kuttaka* method is applied.

Equation 1 can be rewritten as an (equivalent) “congruence” relation modulo the integer q , namely as $px \equiv m \pmod{q}$; we might recall here the customary notation, for a, b, c in $\mathbf{Z}$, that $a \equiv b \pmod{c}$ exactly when c divides $a-b$. Whenever d , the g.c.d. of p and q divides m , we can find, by Euclid's algorithm, an integer x such that $px-m$ (equals qy and hence) is divisible by q , i.e., $px \equiv m \pmod{q}$. The *kuttaka* precisely enables one to find the form of the general solution of this congruence (whenever (p, q) divides m). Take, by way of an example, the congruence $3x \equiv 1 \pmod{7}$. Since the g.c.d. $(3, 7)$ equals 1, the congruence is indeed solvable. Now $3 \times (-2) = -6 \equiv 1 \pmod{7}$ and so, on multiplying both sides of the congruence by -2 , we get $-6x \equiv -2 \pmod{7}$ which is the same as $x \equiv 5 \pmod{7}$. The *kuttaka* thus tells us that any integer of the form $7n + 5$ for arbitrary n in $\mathbf{Z}$ satisfies the congruence $3x \equiv 1 \pmod{7}$.

From linear equations in x and y , let us move on to (much more non-trivial) equations of degree 2 in two variables, e.g. $x^2 - Ny^2 = 1$ for N in $\mathbf{N}$. If $N = M^2$ with $M \in \mathbf{Z}$, the solution in integers x, y of this equation can be immediately found by factorising the left hand side and rewriting the equation as $(x + My)(x - My) = 1$ and hence as $(x + My) = (x - My) = \pm 1$. However, if $N = 2$ or any square-free integer (i.e. not divisible by the square of any prime number), then one could ask for all integers y such that $Ny^2 + 1$ is the square of an integer and, in other words, ask for solutions in integers x, y of

$$x^2 - Ny^2 = 1 \quad (2)$$

which indeed looks harder and is known as Pell's equation (ever since Euler attached Pell's name to it by mistake!).

For a while, let the square-free integer $N > 1$ be kept fixed in our general discussion and let, for any given integer m , the given triple $(x, y; m)$ stands for a solution in integers x, y of the more general diophantine equation

$$x^2 - Ny^2 = m \quad (3)$$

We can clearly identify, for any $t \neq 0$ in $\mathbf{Z}$, the triple $(tx, ty; t^2m)$ with $(x, y; m)$.

Under the heading *Vargaprakrti*, (Eq. 3) was investigated by the Indian mathematician ► **Brahmagupta** (seventh century AD) who used his *bhavana* rule to get non-trivial solutions for (Eq. 2) in integers for several cases of N (and, in particular, for $N = 92$ or 83 , solutions given by $(1151)^2 - 92 \times (120)^2 = 1, (82)^2 - 83 \times 9^2 = 1$. The *bhavana* (composition) rule gives, for two given triples $(x, y; m)$ and $(z, t; n)$, their product (or composite) $(x, y; m)(z, t; n)$ by the formula

$$(x, y; m)(z, t; n) := (xz \pm Nyt, xt \pm yz; mn) \quad (4)$$

Written in expanded form, this leads us to the composition formula

$$\begin{aligned} & (x^2 - Ny^2)(z^2 - Nt^2) \\ &= (xz \pm Nyt)^2 - N(xt \pm yz)^2 \end{aligned} \quad (5)$$

expressing, in modern parlance, the multiplicative property of the norm form $x^2 - Ny^2$ in two variables x and y .

The square-free integer N associated with the triple $(x, y; m)$ for (Eq. 3) was referred to as the *gunaka* (or *prakrti*) and the integer m therein as *ksepa* (additive). Brahmagupta knew how composition of a triple $(x, y; m)$ with a triple $(p, q; 1)$ with the same *gunaka* N leads to a triple $(x', y'; m)$, while the product $(x, y; m)(x, y; m)$ is again a triple $((x^2 + Ny^2)/m, 2xy/m; 1)$ provided $(x^2 + Ny^2)/m$ and $2xy/m$ are both in $\mathbf{Z}$. For $m = -1$ or ± 2 , composition of $(p, q; m)$ with itself leads to $(p^2 + Nq^2, 2pq; 1)$ or $((p^2 + Nq^2)/2, pq; 1)$, respectively. While the composition formula (Eq. 5) occurs explicitly in

Brahmagupta's work, special cases of the same for $N = 3$, $z = 5$, $t = 3$ may have been applied by Archimedes to obtain approximations to $\sqrt{3}$ by rational numbers, according to Weil.

We now give an example to see how the *bhavana* rule helps in solving (Eq. 2). Let us take Brahmagupta's investigation of the case $N = 83$ itself. The natural number "closest" to the *vargamoola* (square root) $\sqrt{83}$ of 83 is 9 and the relation $9^2 - 83 \times 1^2 = -2$ is the same as the triple $(9, 1; -2)$ corresponding to the value 83 for N . Composing this triple with itself according to *bhavana* as in (Eq. 4), we note that $((9 \times 9) + (83 \times 1 \times 1))^2 - 83((9 \times 1) + (9 \times 1))^2 = 4$, giving the "square" of $(9, 1; -2)$ as $(164, 18; 4)$. On division throughout by 4, the last-mentioned triple leads exactly to $(82, 9; 1)$ which is a solution (as discovered by Brahmagupta) for (Eq. 2) with $N = 83$. In H. T. Colebrook's book, *Algebra with Arithmetic and Mensuration, from the Sanscrit of Brahmagupta and Bhāscara*, one can find an entire section dealing with Brahmagupta's investigations on *Vargaprakrti*. Brahmagupta could find extremely accurate values for $\sqrt{N}$ using his solutions for (Eq. 2). According to Ian G. Pearce (2002), "this contribution is of huge interest as it is essentially the same method rediscovered and used by Newton and Raphson around 1690, which is known as the Newton-Raphson iterative method".

Despite Brahmagupta's admirable results, the general solution of (Eq. 2) is still not at hand! The brilliant *cakravālā* (cyclic) method for the general solution of (Eq. 2) has been located in the work of Bhaskara much later, around the twelfth century. Almost the same description of the *cakravālā* is provided in a commentary written around the eleventh century by "an otherwise unknown author" Jayadeva, leaving it open (for anyone) to identify the real inventor of the *cakravālā*. We shall now give a brief description of the method and an illustrative example.

The idea of the method is to start from a triple $(p_0, q_0; m_0)$ with "small" m_0 and use the *bhavana* to get a triple $(p_1, q_1; m_1)$ with m_1 "small" again and eventually, in finitely many steps, hit upon a triple $(u, v; r)$ with $r = 1, -1, \pm 2$; for $r = 1$,

(Eq. 2) is solved with $x = u$, $y = v$ but in the three remaining cases of r , composition of $(u, v; r)$ with itself yields a solution for (Eq. 2) as explained earlier (noting that the *gunaka* N is kept fixed all the while). For the triple $(p_0, q_0; m_0)$ at the start, p_0 is chosen such that p_0^2 is the square closest to N and q_0 is taken as 1 so that $m_0 = p_0^2 - N$. Next, the integer x_0 is chosen to satisfy the congruence $x_0 \equiv -p_0 \pmod{m_0}$ besides ensuring at the same time that $x_0^2 - N$ is "small" and in fact, more precisely, least in absolute value among all possible choices for x_0 with $x_0 \equiv -p_0 \pmod{m_0}$. Then the triple $(p_1, q_1; m_1)$ is defined as the composite

$$(p_0, q_0; m_0)(x_0, 1; x_0^2 - N) \\ = \left(\frac{(p_0 x_0 \cdot N)}{m_0}, \frac{(p_0 + x_0)}{m_0}, \frac{(x_0^2 - N)}{m_0} \right)$$

which is a genuine triple due to our congruence condition on x_0 . If we note that $x_0^2 - N = m_0 m_1$, we may see that keeping $N - x_0^2$ "small" helps to keep also m_1 "small". The next step in the *cakravālā* is to find x_1 in $\mathbf{Z}$ so as to enable us to obtain the composite $(p_1, q_1; m_1)(x_1, 1; x_1^2 - N)$ is a genuine triple to be defined as $(p_2, q_2; m_2)$. Actually x_1 is to satisfy the congruence $q_1 x_1 \equiv -p_1 \pmod{m_1}$ as well as the condition that $x_1^2 - N$ is "small" (i.e. least in absolute value among possibilities for x_1 got by using *kuttaka*). Having got the triple $(p_2, q_2; m_2)$, one proceeds to find suitable x_1 (modulo m_2) to move on to a triple $(p_3, q_3; m_3)$ and eventually, as mentioned above to a solution of (Eq. 2).

Example. For $N = 31$, we have $p_0 = 6, q_0 = 1, m_0 = 5$ giving us (in the terminology of Bhaskara) the (corresponding) auxiliary equation $31 \times 1^2 + 5 = 6^2$. Then by Bhaskara's lemma (i.e. indeed composing $(6, 1; 5)$ with $(x_0, 1; x_0^2 - 31)$ so that $x_0 \equiv -6 \pmod{5}$ and further the absolute value of $x_0^2 - 31$ is least (among all integers x_0 congruent to -6 modulo 5), we obtain $x_0 = 4$ and $(p_1, q_1; m_1) = (6, 1; 5)(4, 1, -15) = (11, 2; -3)$. Next with the auxiliary equation $31 \times 2^2 - 3 = 11^2$, *kuttaka* is used to find x_1 with $2x_1 \equiv -11 \pmod{3}$ and $x_1^2 - 31$ least (in absolute value), yielding

$x_1 = 5$ and $(p_2, q_2; m_2) := (p_1, q_1; m_1)(5, 1; -6) = (-39, -7; 2)$. Since $m_2 = 2$, a shortcut via the *bhavana* is to define directly $(p_3, q_3; m_3) := (-39, -7; 2)(-39, -7; 2) = (-1, 520, -273; 1)$, solving $x^2 - 31y^2 = 1$ at once. On the other hand, one could follow the general method indicated in the preceding paragraph to get $x_2 = 5$ and the triples $(-39, -7; 2)(5, 1, -6) = (-206, -37; -3)$, $(-657, -119; 5), (-1, 520, -273; 1)$ in that order. Further iteration of the method not only yields more and more solutions for $s^2 - 31y^2 = 1$ but also reveals a “cyclic” pattern in the *additives* m_i (vindicating the chosen name *cakravāla*). Using familiar notation for periodic simple continued fractions for quadratic irrationalities (e.g. Davenport 1990, pp. 104–105), we write $\sqrt{31} = \langle 5\overline{1, 1, 3, 5, 3, 1, 1, 10} \rangle$ and the relevant *convergent* $\langle 5, 1, 1, 3, 5, 3, s, 1, 1 \rangle = 1520/273$ got by omitting the *partial quotient* 10 from the *very* first period $\overline{1, 1, 3, 5, 3, 1, 1, 10}$ gives the same solution for (Eq. 2) as above. Weil’s own version of the *cakravāla* has the merit of not only totally dispensing with the use of *kuttaka* (in Bhaskara’s exposition of the *cakravāla*) but also making the “cyclic” pattern in the occurrence of the *additives* m_i quite transparent and *in tune with* the phenomenon of *periodicity* in the continued fraction expansion for $\sqrt{N}$. Are not the triples $(1, 766, 319, 049, 226, 153, 980; 1)$ for $N = 61$ and $(48, 842, 5, 967; 1)$ for $N = 67$ discovered and offered to us by Brahmagupta and Bhaskara masterpieces adorning the lustrous history of *cakravāla*?

To be fair though, one should recall Weil’s remarks that a rigorous treatment as explained above for constructing the successive triples $(p_i, q_i; m_i)$ “may have been known to Indian mathematicians only experimentally and there is nothing to indicate whether they had proof for them, or even part of them” and again that “For the Indians, of course, the effectiveness of *cakravāla* could be no more than an experimental fact, based on their treatment of a great many special cases, some of them of considerable complexity and involving (to their delight, no doubt) quite large numbers. Fermat was the first to perceive the need for a general proof and Lagrange the first to publish one. Nevertheless, to have

developed the *cakravāla* and to have applied it successfully to such difficult cases as $N = 61$ or $N = 67$ had been no mean achievement”. Weil is unsparing as well in his critical analysis of Euler’s contribution to the topic of “Pell’s equation” in the form of drawing attention to the periodicity and “palindromic” property of the “partial quotients” in the continued fraction expansion for $\sqrt{N}$ or their use in solving “Pell’s equation” with perhaps merely experimental evidence to back up his assertions. Although the “Cattle Problem of Archimedes” (Davenport 1990) is usually associated with Pell’s equation, one learns from Weil that equations such as (Eq. 2) “do occur in Diophantus. . . , but it is a rational solution that is asked for, even when accidentally a solution in integers is obtained. . . .”. A detailed discussion of Kronecker’s interesting solution (using elliptic functions) for Pell’s equation can be found in Siegel’s section 27.1 (1963).

Calculus

C. K. Raju

Centre for Studies in Civilizations, New Delhi, India

Al-Bukhari International University, Alor Setar, Malaysia

The Indian origin of infinite series, found in widely distributed texts, has long been publicly known to Western scholars (Whish, 1832).

Recent research (Raju, 2007) has shown that these Indian developments really did amount to the calculus. (This brings to the forefront various epistemological issues, and the very philosophy of mathematics taken for granted in Western discourse.) This research has also pushed the historical origin of the calculus in India much further back to the fifth century CE Āryabhaṭa and his method of obtaining sine values by numerically solving the corresponding differential equation using a finite difference technique.

The infinite series had originated in India by the fourteenth century. An explicit formula for the sum of an infinite (*anantya*) geometric series is given by the fifteenth and sixteenth centuries Nīlakantha in his *Āryabhaṭīyabhāṣya* (Sastri 1930, commentary on *Gaṇita* 17, p. 142.)

एवं यस्तुल्यच्छेदपरभागपरम्पराया अनन्ताया अपि संयोगः
तस्यानन्तानामपि कल्प्यमानस्य योगस्याद्यावयविनः
परम्परांश्छेदादेकोनच्छेदांशसाम्यं सर्वत्रापि समानमेव ।

which may be translated (cf. Sarma, 1972, p. 17):

The sum of an infinite [*anantya*] series, whose later terms (after the first) are got by dividing the preceding one by the same divisor everywhere, is equal to the first term multiplied by the common divisor and divided by one less than the common divisor.

That is $a + \frac{a}{d} + \frac{a}{d^2} + \dots = \frac{ad}{d-1}$. (It is assumed that the divisor $d > 1$, so that the common ratio is less than 1.) This is obviously the earliest textual source in the world for a formula for a properly infinite sum.

Was this infinite sum based on a “rigorous” notion of limits? In fact, it was based on something superior. Indian mathematicians used a different number system involving what would today be called “non-Archimedean” arithmetic and a different epistemology, which allowed discarding of infinitesimals (see also “► Zeroism”).

In terms of formal mathematics, the Indian approach may be understood as follows. Ever since algebra began (with Brahmagupta), Indian mathematicians referred to polynomials as “unexpressed (*avyakta*) numbers.” This led naturally to “unexpressed fractions,” or what formal

mathematicians would today call the non-Archimedean ordered field of rational functions. (For an elementary construction of this field, see Moise, 1968, Appendix.)

A non-Archimedean field contains a number x such that $x > n$ for every integer n . Such a number may be called infinite. Being a field, it also contains the multiplicative inverse of the number which satisfies $0 < \frac{1}{x} < \frac{1}{n}$ for every integer n , so that $\frac{1}{x}$ may be called infinitesimal. The existence of infinitesimals means that limits are not unique, and one must discard infinitesimals. (“Infinitesimal” does *not* mean the same thing as “imperceptible” or “intangible,” e.g., $\frac{3}{n}$ or $\frac{n}{n^2}$ are infinitesimals.) The traditional Indian process of summing infinite series by discarding of infinitesimals, as used in deriving the above formula, is equivalent to limits by order counting (Raju, 2007, Chapter 3).

Discarding infinitesimals is related to discarding small numbers, but clearly goes a step beyond it. Small numbers were traditionally discarded, from at least 2,500 years ago, since the days of the *śulba sūtra* to provide “approximate” values of $\sqrt{2}$, π , etc. The terms then used were *saviśeṣa* (with something remaining) (Baudhāyana *śulba sūtra*, 2.12 1, Sen & Bag, 1983, p. 169), *anitya* (impermanent) (Apastamba *śulba sūtra*, 3.2, Sen & Bag) in the *śulba sūtra*, and *āsanna* (near value) by Āryabhaṭa (*Gaṇita*, 10, Shukla & Sarma, 1976). This was similar (but not identical) to the way one today has no choice but to discard small numbers in computer (floating point) arithmetic, since a computer cannot physically implement formal “real” numbers obtained as metaphysical limits.

Further, since Āryabhaṭa (fifth century), at least, an algorithm was available for square root extraction, so there was a recursive process of generating an infinite series for, say, $\sqrt{2}$. A recursive series for difficult fractions, similar to continued fractions, was also used since Brahmagupta. (For full details, and for the use of this fraction-series expansion in developing later-day infinite series, see Raju, 2007, Chapter 3.) Summing an infinite series, as Nīlakanṭha did, by discarding infinitesimals, or

order counting, clearly goes beyond the much older process of discarding small quantities by truncation of infinite series or halting those recursive procedures after a finite number of steps.

Further, one should not just assume that metaphysical limits or Western metaphysical ways of handling infinity are automatically superior. Thus, the use of non-Archimedean arithmetic (plus zeroism) leads to a notion of derivative superior to the present-day college-text definitions of the derivative as a limit, for the college-text definition fails with a discrete number system like floating point numbers on a computer, or with discontinuous functions. While the Schwartz theory does allow a discontinuous function to be differentiated, Schwartz distributions cannot be readily multiplied; therefore, that notion of derivative cannot be used for nonlinear differential equations of physics (Raju, 1989).

The whole problem of how to define the derivative or the notion of probability has a natural and very simple resolution using Indian “non-Archimedean” arithmetic and the related philosophy of zeroism, a solution which is better and far simpler than the resolution using nonstandard analysis, as was used earlier (Raju, 2007, Appendix).

Further, it is clearly wrong to assume that the dominant philosophy of formalism, even though globalized by colonialism, represents a universal philosophy of mathematics or is the only correct way to do mathematics. Even the logic underlying mathematical proofs is not universal (Raju, 2001; see also article on “► Logic”). Formalist philosophy hence involves a biased metaphysics (Raju, 2011b).

Calculus can also be taught with a different philosophy which follows its actual historical development and makes it easy to learn. (Thus, over the last few years, “decolonized” courses on “calculus without limits” have been taught with significant success to eight groups in four universities in three countries; Raju, 2011c, 2012.)

Indian mathematicians long knew about *finite* geometric series, which they called *guṇottara sankalitā* or *guṇottara śreḍhī* (multiplicative series), and methods of summing the finite geometric series were a part of the elementary school

curriculum from at least 1,300 years ago and are found in numerous elementary texts such as the *Pāṭi Gaṇita* of Śrīdhara (Śrīdhara, Shukla, 1959, trans. p. 75.) Indeed, summing a finite multiplicative series was a very common commercial problem found in a variety of other sources such as the *Gaṇita Sāra Saṁgraha* of Mahāvīra (Jain, 1963), *Mahā Siddhānta* of Āryabhaṭa II (Dwivedi, 1900), the *Līlāvātī* of Bhaskara II, etc. (rule 126 et. seq; the numbering differs between Colebrooke, 1816 and the critical edition of Sarma, 1975).

In fact, the place value system lends itself naturally to “geometric” (multiplicative) series, and the first such series is found thousands of years earlier in the Yajurveda (17.2), and in the Lalita Vistara Sutra (Chapter 12) where it goes up to large numbers like 10^{53} (named *tallakṣaṇa*).

Of what use were these infinite series? An infinite series expansion for the sine and cosine (today called the “Taylor” series, after a pupil of Newton) was used by Madhava of Sangamagrama (1340 CE) to calculate precise sine and cosine values, by truncating the series to 11th- and 12th-order polynomials. The infinite series expansion is found in two verses stated in various texts, such as the *Tantrasaṁgraha Vyākhyā/Yuktidīpikā* (2.440 – 443) (Sarma, 1977).

निहत्य चापवर्गेण चापं तत्तत्फलानि च ।
हरेत् समूल्युग्वर्गैस्त्रिज्यावर्गहतैः क्रमात् ॥ ४४० ॥
चापं फलानि चाधोऽधो न्यस्योपर्युपरित्यजेत् ।
जीवाप्त्यै, संग्रहोऽस्यैव विद्वान् इत्यदिना क्रितः ॥ ४४१ ॥

This verse may be translated:

Multiply the arc by the square of the arc, and take the result of repeating that [any number of times]. Divide [each of the above numerators] by the squares of successive even numbers increased by that number [lit. the root] and multiplied by the square of the radius. Place the arc and the successive results so obtained one below the other, and subtract each from the one above. These together give the *jīvā*, as collected together in the verse beginning with “*vidvān*” etc.

In present-day mathematical terminology, the above passage says the following. Let r denote the radius of the circle, let s denote the arc, and let t_n denote the n th expression obtained by applying

the rule cited above. The rule requires us to calculate as follows.

1. Numerator: multiply the arc s by its square s^2 , this multiplication being repeated n times to obtain $s \cdot \prod_1^n s^2$.
2. Denominator: multiply the square of the radius, r^2 , by $[(2k)^2 + 2k]$ ("the squares of successive even numbers increased by that number") for successive values of k , repeating this product n times to obtain $\prod_{k=1}^n r^2 [(2k)^2 + 2k]$.

Thus, the n th iterate is obtained by

$$t_n = \frac{s^{2n} \cdot s}{(2^2 + 2) \cdot (4^2 + 4) \cdot \dots \cdot [(2n)^2 + 2n] \cdot r^{2n}}. \quad (1)$$

The rule further says

$$j\bar{iv}\bar{a} = s - t_1 + t_2 - t_3 + t_4 - t_5 + \dots \quad (2)$$

$$= s - \frac{s^3}{r^2 \cdot (2^2 + 2)} + \frac{s^5}{r^4 (2^2 + 2) (4^2 + 4)} - \dots \quad (3)$$

Substituting

- (1) $j\bar{iv}\bar{a} \equiv r \sin \theta$,
- (2) $s = r \theta$, so that $s^{2n+1}/r^{2n} = r \theta^{2n+1}$, and noticing that
- (3) $[(2k)^2 + 2k] = 2k \cdot (2k + 1)$, so that
- (4) $(2^2 + 2) (4^2 + 4) \dots [(2n)^2 + 2n] = (2n + 1)!$, and cancelling r from both sides, we see that this is entirely equivalent to the well-known infinite series

$$\sin \theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \dots \quad (4)$$

A similar rule gives another infinite series for $\bar{s}ara$, corresponding to the infinite series for cosine. A similar series was available for the inverse arc-tangent function, and various other infinite series

were developed in the process of accelerating convergence of these series (Raju, 2007, Chapter 3).

The above infinite series was used to devise a numerically efficient formula (Raju, 2007, Chapter 3) which finally leads to the table of 24 sine values accurate to the third sexagesimal minute (*tatparā*) and stated in reverse-sexagesimal *kaṭapayādi* notation. (For a detailed explanation of this *kaṭapayādi* system and the precise accuracy of the values, see Raju, Chapter 3.) The first few and last few lines of the verse are as follows

श्रेष्ठ नाम वरिष्ठाना हिमाद्रिवेदभावनः ।

तपनो भानुसूक्तज्ञो मध्यमं विद्धि दोहनम् ॥

धिगाज्यो नाशनं कष्टं छन्नभोगाशयाम्बिका ।

म्रिगाहारो नरेशोऽयं वीरो रणजयोत्सुकः ॥

...

छायालयो गजो नीलो निर्मलो नास्ति सत्कुले ।

रात्रौ दर्पणमभ्राङ्गं नागस्तुङ्गनखो बली ॥

धीरो युवा कथालोलः पूज्यो नारीजनैर्भगः ।

कन्यागारे नागवल्ली देवो विश्वस्थली भृगुः ॥

तत्परादिकलान्तास्तु महाज्या माधवोदिताः ।

स्वस्वपूर्वविशुद्धे तु शिष्टास्तत्खण्डमौर्विकाः ॥ २.९.५ ॥

This corresponds to the values in Table 1.

The accuracy of these values in decimals is given in Table 2.

The actual calculation requires the value of the number today called π . Madhava had obtained the value accurate to 12 decimal places. This was obtained by accelerating the convergence of various slowly convergent series such as the infinite series today wrongly called "Leibniz series." Nīlakaṇṭha, in his *Āryabhaṭīya Bhaṣya*, in his commentary on *Gaṇita* 10 (Sastri, 1930, p. 56), described the subtle value of π given by Madhava of Sangamagrama as follows:

सङ्गमग्रामजो माधवः पुनरत्यासन्नं परिधिसंख्यामुक्तवान् -

विवुधनेत्रगजाहिहताशनत्रिगुणवेदभवारणबाहवः ।

नवनिखर्वमिते वृत्तिविस्तरे परिधिमानमिदं जगदुर्वुधाः ॥

The numbers in this verse are according to the old *bhūta saṁkhyā* system, which uses word

Calculus, Table 1 Madhava's sine values

No.	Kaṭapayādi	kalā (')	vikalā('')	tatparā('')

Calculus, Table 2 Accuracy of Madhava's sine table

No.	Mādhava's sine value	Difference
1	0.0654031452	0.0000000160
2	0.1305262297	0.0000000375
3	0.1950903240	0.0000000020
4	0.2588190035	-0.0000000416
...	...	...
...	...	...
21	0.9807852980	0.0000000176
22	0.9914448967	0.0000000353
23	0.9978589819	0.0000000587
24	1.0000000000	0.0000000000

numerals. Thus, *netra* means 2 because one has two eyes, *veda* = 4, *guṇa* = 3, *tri* = 3, etc. (For more details about the *bhūta saṁkhyā* system, see Datta & Singh, 1935.) The quantity *nikharva* = 10^{11} . Thus, the above verse may be translated:

Mādhava of Saṅgamagrāma spoke the approximate [*āsanna*] number of the circumference of a circle:

vibudha [33] *netra* [2] *gaja* [8] *ahi* [8] *hutāśana* [3] *tri* [3] *guṇa* [3] *veda* [4] *bhavāraṇa* [27] *bāhavaḥ* [28], i.e., [2,827,433,388,233] is the measure of a circle of diameter *nava* [9] *nikharva* [100,000,000,000].

This corresponds to $\pi = 3.141,592,653,5922$..., accurate to 11 places after the decimal point, with the 12th and 13th places (92 respectively) differing slightly from their accurate value (89). The term *nikharva* continues the series, *koṭi*, *arbuda*, *abja*, *kharva*, *nikharva*, then in common use for centuries. (*Pāṭi Gaṇita*, 7. Shukla, 1959.) Parts of this series coming from Vedic times are still in current use, e.g., *koṭi* = crore. (Currently, an *arbuda*, called “arab,” is 100 crores, while a *kharva*, called “kharab,” is 100 arabs.) The more common expression for π stated in the *kaṭapayādi* system, using reverse-sexagesimal notation, gives the radius of a circle with circumference 21,600 (= number of minutes in 360°) as *Devo viśvasthalī bhr̥guḥ*, corresponding (in reverse order) to 3437' 44" 48", which is

substantially more accurate than the seventh-century Bhāskara's figure of $3438'$, or the ninth-century Vateśvara's figure of $3437' 44''$.

As is clear from the above figures, these methods developed gradually over a thousand years, as the requirements of precision gradually increased. These accurate trigonometric values were needed for astronomy used for the practical needs of the calendar and navigation. The calendar was needed for successful monsoon-driven agriculture, in India, while navigation was needed for overseas trade. The whole tradition of computing 24 sine and cosine values, 3.75° apart, was started a thousand years earlier by Āryabhaṭa in the fifth century. He computed 24 sine values and the value of π accurate to the first sexagesimal minute (*kalā*, about 5 decimal places). It is well known that Āryabhaṭa's value of π was quoted by al Khwārizmī, but not so well known that this was still being repeated by sixteenth-century European navigational theorists, such as Simon Stevin (Pannenkoek & Crone, 1961).

Calculus Transmission

C. K. Raju

Centre for Studies in Civilizations, New Delhi,
India

Al-Bukhari International University, Alor Setar,
Malaysia

It has gone unnoticed that Āryabhaṭa's 24 sine values (see “► [Calculus](#)”) involved a striking departure from the earlier geometric tradition and a paradigm shift to numerical techniques. The geometric tradition is useful only in simple situations where high symmetry is present. It cannot be used to calculate the sine of 1° but was earlier used to compute 6 sine values 15° apart.

In a second radical departure, Āryabhaṭa used difference equations, instead of algebraic equations. Indeed, in the tenth *gītikā* (this is called the tenth *gītikā* since the first two are invocations; Shukla & Sarma, 1976), of the *daśgītikā* section, he states only the sine *differences*:

मखि भखि फखि धखि राखि जखि
डखि हस्म स्ककि किषा श्चकि किच्च ।
ब्लकि किग्र हक्व धकि किच
स्ग श्म ड्व क्ल प्त फ छ कलार्धज्या ॥ १२ ॥

The numbers involved here are expressed in Āryabhaṭa's novel numerical notation (see Shukla & Sarma, 1976 or Raju, 2007, Chap. 3). Thus, the verse may be translated:

225, 224, 222, 219, 215, 210, 205, 199, 191, 183, 174,
164, 154, 143, 131, 119, 106, 93, 79, 65, 51, 37, 22,
7—[these are the] sine [lit. half-chord] differences
[for the quadrant divided into as many equal parts,
each part hence being $225'$] [in] minutes.

The method of calculating these differences is explained in Gaṇita 12 as:

प्रथमाच्चापज्यार्धाद्यैरूनं खरिडतं द्वितियार्धम् ।
तत्प्रथमज्यार्धाशैस्तैस्तरूनानि शेषाणि ॥ १२ ॥

This may be translated:

(12) The sine of the first arc divided by itself and diminished gives the second sine difference. That

same first sine, when it divides successive sines gives the remaining [sine differences]. (Trans. by the author, based on the Hindi translation of Rai, 1976, pp. 42–43; cf. Shukla & Sarma, 1976, p. 51)

That is, if the quadrant of the circle is divided into, say, 24 equal parts, where $R_1, R_2, \dots, R_{24}$ are the 24 corresponding sine values; $\delta_1 (= R_1)$, $\delta_2, \dots, \delta_{24}$ are the corresponding sine differences; and $\delta_i = R_i - R_{i-1}$, for $i \geq 2$, then Āryabhaṭa's rule consists of the following two parts:

$$\delta_2 - \delta_1 = -\frac{R_1}{R_1}, \quad (1)$$

$$\delta_{n+1} - \delta_n = -\frac{R_n}{R_1}. \quad (2)$$

This cannot be understood as an algebraic equation, since that would lead to the wrong answers. More precisely, it can be regarded as an algebraic equation for calculating the second difference but not for its proper purpose, which is to calculate sine differences (Raju, 2007).

Āryabhaṭa's technique of solving those difference equations was later modified by Nīlakaṇṭha to make it accurate to thirds. Thus, the above interpretation is also the one given by Nīlakaṇṭha in his *Āryabhaṭīyabhāṣya* (Sastri, 1930), except that Nīlakaṇṭha makes it more precise, by stating it in the form

$$\delta_n^{(2)} = -\left(\frac{R_n}{R_1}\right) (\delta_1 - \delta_2). \quad (3)$$

The difference here is that for Āryabhaṭa, working to the precision of minutes, $\delta_1 - \delta_2 = 225 - 224 = 1$, while this is no longer the case with Nīlakaṇṭha, working to the precision of thirds, who uses the values, $R_1 = [224; 50; 22]$ and $R_2 = [448; 42; 58]$, so that $\delta_2 = [223; 52; 36]$ and $\delta_1 - \delta_2 = [0; 57; 46]$.

Āryabhaṭa's method of solving differential equations by finite differences is today wrongly called “Euler's method” after Euler who studied the relevant Indian texts when he wrote an article on the Indian calendar in 1700. Further, the numerical solution of differential equations (rather than metaphysical existence and

uniqueness theorems) is at the heart of all practical applications of the calculus even today.

Āryabhaṭa's process of setting up and solving differential equations involves only the simple "rule of 3" or what would geometrically be called linear interpolation. However, unlike the geometric notion, the arithmetic process easily extends recursively, and recursive application of this process naturally leads to second- and higher-order differences and thence to the infinite series used by Madhava and others.

Note that Āryabhaṭa himself brought in the *second* difference. Today, we would rewrite the formula as

$$\delta_n^{(2)} \equiv \delta_{n+1} - \delta_n = -\frac{R_n}{R_1}, \quad (4)$$

corresponding to the idea that the second difference/derivative of the sine is proportional to the sine itself. But with finite differences, a little more detail is necessary, and Āryabhaṭa also specifies the constant of proportionality.

Second differences were also used for interpolation, from Brahmagupta onwards, about a century later, and this use was continued subsequently by Vaṭeśvara and Bhāskara II.

Brahmagupta's second-order interpolation formula, nowadays wrongly called "Stirling's formula," is stated as follows (*Uttarakhaṇḍ-akhādyaka*, II.1.4, Chatterjee, 1970, vol. II, p. 177).

गतभोग्यखण्डकान्तरदलविकल वधाच्छतैर्नवभिराप्त्या ।
तद्युतिदलं युतोर्न भोग्यादूनाधिकं भोग्यम् ॥ ४ ॥

This has been translated (using Bhaṭṭotpala's tenth century CE [Saka 888] commentary) as:

Multiply the *Vikalā* by half the difference of the *Gatakhanda* and the *Bhogyakhanda* and divide the product by 900. Add the results to half the sum of the *Gatakhanda* and the *Bhogyakhanda*, if their half sum is less than the *Bhogyakhanda*; subtract, if greater. [The result in each case is the *Sphuṭabhogyakhanda* or correct "tabular" difference.]

Here, the underlying table is that calculated for *khaṇḍajyā*-s or sine differences for intervals that are spaced h apart, where it is assumed that

$h = 15^\circ$ or $900'$. The *gatakhanda* or "past difference" ($= \delta_n$) refers to the interval that has been crossed, and the *vikalā* ($= \theta$) is the amount in minutes by which it has been crossed at the point at which we want to interpolate. The *bhogyakhanda* ($= \delta_{n+1}$) is the one yet to come. Thus, the formula states:

Sphuṭabhogyakhanda

$$= \frac{\delta_n + \delta_{n+1}}{2} \pm \frac{\theta}{h} \frac{\delta_n - \delta_{n+1}}{2} \quad (5)$$

$$\sin(nh + \theta) - \sin nh = \frac{\theta}{h} \times \text{sphuṭabhogyakhanda}. \quad (6)$$

This amounts to

$$\begin{aligned} \sin(nh + \theta) &= \sin nh + \frac{\theta}{h} \frac{\delta_n + \delta_{n+1}}{2} \\ &\quad \pm \frac{\theta^2}{h^2} \frac{\delta_n - \delta_{n+1}}{2}. \end{aligned} \quad (7)$$

Vaṭeśvara (*Siddhānta*, II.1.63 – 82) (in 904 CE) uses backward differences, works with arcs that are only $56' 15''$ apart, and still uses quadratic interpolation, explicitly giving the second of the above formulae, among many others (Shukla, 1976, part I, p. 96, and part II, p. xlv). This enabled him to improve Āryabhaṭa's sine values (accurate to the minute) and achieve accuracy to seconds.

Bhāskara II, while offering a justification for these formulae stated by Vaṭeśvara, brings in the present or instantaneous sine difference as the mean value of the past and future sine difference. This concept of *tātkālika bhogya khanda* or instantaneous difference leads him naturally to the concept of *tātkālika gati* or *instantaneous velocity* of a planet, since it is in that context of planetary motion that these interpolations were typically required (*Siddhānta Śiromaṇi*, *Spaṣṭādhikāra* 36–38, and accompanying autocommentary *Vāsanābhāṣya*, Sastri, 1858, 1929, 1939, 1943; Sengupta, 1932). This notion of derivative used for planetary velocity (*gati*) is not a "precursor" to the Newtonian notion, using

fluxions, but involves an understanding of the derivative which is superior from both a practical and an epistemological perspective, as explained earlier.

The calculus in India was also used to derive accurate formulae for areas and volume – a typical application of present-day integral calculus. The volume of a sphere was first correctly expressed by Śrīdhara in his *Triṣaṭikā* (Dwivedi, 1899; Ramanujachari and Kaye 1912).

Bhāskara II suggests a very interesting pedagogical demonstration, involving a model of the earth made of clay or wood.

He concludes:

This is as I have said in my Arithmetic: (*Lilāvātī*, rule 201; Sarma, 1975) the area of a circle is equal to the product of the circumference by one-fourth of the diameter [πr^2]. That result multiplied by 4 gives the surface of the sphere [$4\pi r^2$], which is like the net surrounding a hand ball; the same (surface of a sphere) when multiplied by the diameter and divided by six [$\frac{4}{3}\pi r^3$] becomes invariably the volume of the sphere.

These correct formulae for the surface area and volume of a sphere are significant, since the correct formulae for the volume of a sphere were not known earlier.

The term “Kerala school,” used by the late K. V. Sarma, has been misused to suggest that calculus originated solely in Kerala. As we have seen, the whole technique of numerically solving differential equations began with Āryabhaṭa who did this work in Kusumpura or Patna. K. V. Sarma, himself, denied that Āryabhaṭa was somehow from Kerala (Sarma, 2001). Further, as the title of Nīlakaṇṭha’s *Āryabhaṭīyabhāṣya* says, Nīlakaṇṭha regarded himself as belonging to the Āryabhaṭa school. This is also significant since Nīlakaṇṭha, as his name “somasūtvān” says, was a Brahmin of the highest caste, while Āryabhaṭa, as his name “bhaṭa” indicates, belonged to a low caste. (“Bhaṭa” meaning slave should not be confounded with “bhaṭṭa” which is the appellation of a learned Brahmin.) The Āryabhaṭa school in Kerala clearly shows that neither the caste divide nor the regional divide was as strong then. The development initiated by Āryabhaṭa was continued by a variety of other mathematicians, from Gujarat, Ujjain, and

Banaras. The first infinite/indefinite series was derived by Brahmagupta, as a technique for approximating difficult fractions, in what this author has called the “fraction series expansion” (*Brāhma Sphuṭa Siddhānta* 12.57, more details in Raju, 2007, Chap. 3).

Even more importantly, a key input in the summation of the series was a general formula given by Nārāyaṇa Paṇḍit of Benares in his *Gaṇita Kaumudī* (Dwivedi, 1942, p. 123) for the *vārasaṅkalitā*. (Since Nārāyaṇa is a very common name in India, some scholars have confounded Nārāyaṇa Paṇḍit with some other Nārāyaṇa in the Kerala school.) This *vārasaṅkalitā* series, involving summation of partial sums, is also mentioned by Bhaskara II, who, however, does not give a general formula for summing it. Some five centuries before Mādhava, Govindasvāmin (ca. 800, *Bhāṣya* on the *Mahā Bhaṣkarīya*, iv.22; Sen, 1966, p. 78) and then Udayadivākara (tenth century, *Sundarī* on the *Laghu Bhāskarīya*, ii.3 – 6; Sen, p. 280), of the Āryabhaṭa school in Kerala, tried to obtain trigonometric values accurate to the thirds (i.e., third sexagesimal minute), but their values were not accurate enough; Mādhava’s trigonometric values are however accurate to the thirds. Hence, it is clear that a key input enabling the computation to thirds is the expression for the sum of the *vārasaṅkalitā* given by Nārāyaṇa Paṇḍit of Benares in his *Gaṇita Kaumudī*. Thus, there is no way that the calculus developments can be localized to any one region or caste in India.

What was the social and practical need for such highly accurate sine values? This is related to the two key sources of wealth in India, namely, agriculture and overseas trade. (For a summary account, see GJH, 2007.) Since agriculture in India was (and still is) mostly monsoon driven, it required a good calendar to get the right time of the monsoons, described in the Indian lunisolar calendar by the months of *sawan* and *bhadon*. There is no such possibility in the Gregorian calendar. The Indian calendar was based on a sophisticated astronomical model, similar, but not identical, to the one attributed to the supposed Greek author of the *Almagest* (Raju, 2014).

In this context, some authors refer to the sine as Rsine and claim that trigonometry was transmitted to Indians from the *Almagest*. However, the actual evidence tells us that trigonometry was transmitted from India to Europe via Arabs. Indeed, the very word “sine” derives from a translation howler during the Toledo mass translations of Arabic texts in 1125 CE. The word derives from the Latin *sinus* or fold, which is a translation of the Arabic *jaib*, meaning pocket, which is a wrong reading of the Arabic *jiba*, from the vernacular *jīvā*, for the Sanskrit *jyā*, meaning chord (as used by Āryabhaṭa).

Indeed, scientific texts are accretive, so that the twelfth-century *Almagest* reflects twelfth-century knowledge which came about by transmission from India. There is no serious evidence for either its existence in its present form in the second century CE or that its author was a Roman-Greek called Claudius Ptolemy. The failure to reform the Julian calendar since the fifth century is counterevidence against this belief (Raju, 2010).

The linguistic error of translation in the term “sine” was accompanied by a conceptual error, as in the very word “trigonometry” where the functions relate to the circle, not the triangle. That error persists to this day in the teaching of “trigonometry” which is stuck in the pre-Āryabhaṭa era. The word “trigonometry” is in quotes, since this geometric method wrongly suggests that the concepts of sine and cosine relate to the triangle, whereas they actually relate to the circle.

Studying the movements of planets on the celestial sphere naturally required calculations with the circular functions sine and cosine. Hence, sine tables are commonly found in Indian astronomy and mathematics texts, starting from the third-century CE *Sūrya Siddhānta*. This requirement of an accurate calendar for successful agriculture still persists. (Specifically, on a number of occasions in the last decade, there has been large-scale crop failure due to mistimed agricultural operations; Raju, 2007, Chap. 4.)

Accurate sine values (and an accurate calendar) were also required for navigation even to determine latitude. At night, latitude could be determined simply by measuring the altitude of

the pole star. This was done using a sophisticated instrument (with harmonic interpolation) which was never earlier understood by Western historians (Raju, 2007, Chap. 5). This instrument was used by the Indian navigator who brought Vasco da Gama to Calicut in India from Melinde in Africa. However, Vasco neither knew nor immediately understood the method. Since the Malayalam word for the pole star (*kau*) also means teeth and the instrument used by the navigator is held between the teeth, Vasco da Gama recorded that “the pilot told the distance by his teeth”!

In daytime, latitude was determined from observations of solar altitude at noon, and longitude was determined by solving the appropriate longitude triangles (Raju, 2007, Chap. 4). A solution to these two problems of latitude and longitude determination is found in many early Indian texts, such as the text of the seventh-century Bhaskara I, a commentator on the fifth-century CE Āryabhaṭa.

The seventh-century Bhaskara I explains (*Laghu Bhāskarīya*, III.2-3, Shukla, 1963, p. 42; Raju, 2007, Chap. 4) how to calculate the local latitude (ϕ) from the equinoctial midday shadow (s) using a gnomon of height g using the formula $\tan \phi = \frac{s}{g}$. Note that this formula is useful only if one has a method of computing the arctangent function (or a method of “arcifying” sines), and this explains the need for the infinite series for the arctangent.

The seventh-century Bhaskara I also explains (*Laghu Bhāskarīya*, III.22 – 23) how to calculate the local latitude from the observation of solar altitude at noon, provided also that the solar declination is known. That requires a good calendar which correctly tells the date of the equinox.

Bhaskara I also gives a method of longitude determination, by solving a longitude triangle, from a knowledge of the departure or distance between two points A and B , and the corresponding difference of latitude (*Mahā Bhāskarīya* II.3 – 4, Shukla, 1960, pp. 49–50). He himself criticized the rule, among other reasons, for neglecting the sphericity of the earth and not using spherical triangles.

This solution of the longitude problem required an accurate knowledge of the size of the earth. Columbus underestimated the size of the earth by about 40 %, and the resulting navigational disasters led to the Portuguese ban of 1500 on carrying globes aboard ships. In contrast, most Indian mathematics and astronomy texts also state an estimate of the radius of the earth. This is stated in *yojanas*, and we do not know *exactly* how much a *yojana* was. Nevertheless, we do know that al Biruni came to India, studied astronomy, and reported on Indian astronomy in his tenth-century *Kitab al Hind*. His estimate was stated in Arabic miles and intended to corroborate Khalifa al Mamun's direct measurement of 1° of arc in the desert. This method of calculating the size of the earth (Raju, 2007, Chap. 4) required very accurate sine and cosine values, and it is also the method implicit in the definition of the Arabic *zam* (from the Sanskrit *yāma*), as the "distance from here to the horizon" (Raju, Chap. 5). Al Biruni's error was 0.25 %, compared to the error of 40 % in Columbus' estimate and the error of 25 % in Newton's first estimate (Rizvi, 1979).

Further, in contrast to Indo-Arabic techniques of celestial navigation, the European technique of navigation involved charts. Hence, apart from the issue of latitude and longitude at sea, a key problem of European navigation was that of loxodromes: because a chart is flat while the surface of the earth is curved, holding a straight course in one direction (using a magnetic compass or a straight line joining two stars) does not result in a straight line on the surface of the earth but a curved line, called a loxodrome. The solution to this problem of loxodromes was provided by the Mercator chart which used an old projection technique of Chinese (Dunhuang) star charts (Needham, 1981, pp. 123–124) to map loxodromes to straight lines. Constructing the Mercator chart required an accurate table of secants or, equivalently, accurate sine values. (The formulae for the Mercator projection are widely available; see, e.g., Raju, 2007, p. 339.) An accurate technique of navigation was the biggest scientific challenge in Europe then. Hence, the Jesuits in Cochin were naturally interested in these Indian

texts with accurate sine values. Their college in Cochin helped procure and translate local Indian texts and sent them back to Europe in a repeat of the Toledo model of mass translation of books. In place of the Mozarabs of Toledo, they then had the support of the local Syrian Christian community in the vicinity of Cochin.

The translated Indian texts would naturally have gone first to the Jesuit general. There is ample circumstantial evidence that did happen. Christopher Clavius, who authored the Gregorian calendar reform, also published in his name a table of sines in 1607. Curiously, these were the so-called Rsines, in that they explicitly involved the radius of the circle. Simon Stevin follows the same practice for his secant tables. Curiously, Clavius used the same large number for the radius as used in Madhava's values (Clavius, 1607). Documentary evidence of a connection comes from Clavius' student Matteo Ricci who visited Cochin just prior to the Gregorian reform to get information about Indian methods of timekeeping (Ricci, 1581). The Indian timekeeping or astronomy texts near Cochin contained detailed accounts of the calculus.

On the epistemic test, those who copy do not fully understand what they copy. This is also evidence of transmission: Clavius got the imported sine values explicitly interpolated to build a larger table but did not know enough trigonometry to calculate the size of the earth. Recall that this size was routinely mentioned in Indian texts and that the size of the earth was a key parameter needed for determining longitudes. (The calendar reform only settled the problem of latitudes.)

There is other circumstantial evidence of transmission of calculus to Europe. Clavius' contemporary, Julius Scaliger, is credited with Julian day-number system which is the same as the Indian *ahargana*. Likewise, another contemporary Tycho Brahe, Royal Astronomer to the Holy Roman Empire, produced the Tychonic astronomical model (in which all planets go round the Sun, which itself goes round the earth) which is just a carbon copy of the astronomical model of Nīlakanṭha, stated in his *Tantrasangraha*. Tycho's masonry instruments

(copied from Ulugh Beg's Samarkand observatory) were not accurate enough to make accurate observations of Mars, such as made by Parameswaran over a 50-year period. Nevertheless, Tycho, in those days of the Inquisition, kept some secret documents with which his assistant Kepler decamped, after Tycho's untimely death or murder. Why did Tycho keep mere observations such a secret from his own assistant? How did Kepler, a nearly blind person, arrive at those super-accurate observations, without appropriate instruments (Broad, 1990; Donahue, 1988)?

Likewise, Fermat's challenge problem to European mathematicians, which remained unsolved for long (and was eventually solved by Euler), is taken from an explicitly solved example in Bhaskara's *Bījagaṇita* (87, Colebrooke, 1816, pp. 176–178). Indeed, Bhaskara himself poses it as a challenge, saying “Declare it friend if the method [of solution] be spread over your mind like a creeper.” Thus, in Feb 1657, Fermat (*Ouvres*, p. 332 et seq.) asked European mathematicians to solve the problem $Nx^2 + 1 = y^2$ for a given (positive, non-square) N . As examples, he listed, for the case $N = 3$, that $x = 1$, $y = 2$ are solutions and $x = 4$, $y = 7$ are also solutions. Then he asked for the smallest integer solutions for the case $N = 61$ and $N = 109$. This is today called “Pell's equation,” and the smallest solutions are the numbers $x = 226153980$, $y = 1766319049$ given by Bhaskara II centuries earlier. Given how large these numbers are, an independent rediscovery would represent a fantastic coincidence.

When the Indian calculus first reached Europe, some people like Fermat and Pascal accepted it enthusiastically, while other people like Leibniz did not fully understand it. (Newton, in his anonymous review of his own report, on behalf of the Royal Society, on Leibniz's charge of plagiarism against him, claimed that Leibniz failed to comprehend the infinite series named after him; Newton, 1714.) Descartes too was unable to comprehend how to sum infinite series. Indeed, Descartes opined that the ratio of curved and straight lines was beyond the capacity of the human mind (Descartes, 1996). In India, children were taught

to measure angles as the length of a curved line (the arc) using a flexible string since the days of the śulba sūtra-s (or aphorisms on the string) (Raju, 2009). They could easily straighten the string to compare the length of a curved line with a straight line (and needed to do so to measure the arc in units of the radius).

On the epistemic test, mistakes are proof of transmission. A charitable interpretation of Descartes' blunder is that he was presumably alluding to the infinite series for π , found in Indian texts from long before Leibniz. He thought an infinite series could only be summed by actually carrying out an infinite number of sums and hence regarded an infinite sum as a supertask. Descartes was not the only person who thought thus. Galileo, whose access to the Jesuit archives is well documented, in his letters to Cavalieri (Mancosu, 1996), agreed with this objection and hence eventually left it to his student Cavalieri to take the credit or discredit for calculus.

Newton, himself, claimed credit only for making the calculus rigorous, not for inventing it (though he did claim credit for the sine series). He thought the calculus could be made rigorous by making time metaphysical. Ironically, that was the precise reason why his physics failed (Raju, 1994). Changing that understanding of time/calculus improves physics including the theory of gravitation (Raju, 2012).

Calendars and Timekeeping Around the World

Bryan E. Penprase
Frank P. Brackett Professor of Astronomy,
Pomona College, Claremont, CA, USA

The Origins of Calendars and Timekeeping

The measurement of time catalyzed the development of numbers, mathematics and astronomy, and cosmology, as the first humans began counting days, then hours, then minutes, and seconds of time. The methods of timekeeping vary

by civilization and reflect the belief systems, environment, and mathematics of each culture. A more complete treatment of the entire range of calendars and how they arose from each civilization can be found in Penprase (2010).

Many Native North American groups used changes in vegetation and animal behaviors to set their calendars and named their months based on these annual cycles. Like the Hawaiian and Zuni peoples, observations of the moon, sun, and stars would give the “master clock” to reset the calendar and start a new year. The stellar observations could include noting the position of the Big Dipper (also known as the Plough or Ursa Major) relative to the horizon at the beginning and middle of the night, as is the practice of the Mescalero Apache, who know the Big Dipper as *nahakus* (pivot point) (Farrer 1991, p. 48). The Havasupai tribe began their New Year with the heliacal rising of the stars known as the “the Hoop” (Corona Borealis), which marked the New Year in mid-November. The Maricopa and Cocopa tribes of Arizona believed the stars were literally a hand of the creator, and lines of stars were the imprints of his fingers. These stars also worked like the hands of a clock, indicating seasons when plants such as the cactus are ripe which produce fruit in the summer when the Pleiades (*Xitca'*) appear on the eastern dawn horizon (Miller, 1997, p. 199).

The Chumash tribe from Southern California used a combination of weather indicators, plants, and precise observations of the sun to set their calendar. Each year a multiday solstice ceremony took place near the winter solstice using a portable sun stick that included a carved and decorated stone head that was inclined precisely toward the altitude of the winter solstice sun. A series of solar observatories from Southern California were used to measure the solstice, such as the Burrow Flat Cave, Condor Cave, and Window Cave, where beams of sunlight crossed sun figures painted inside the cave to mark the solstice.

Most cultures realize in their count of days the need to provide a reconciliation between the solar and lunar cycles. Reconciling the number of days

in the lunar month (29.5333) and the number of days in the solar year (365.2422) was a great challenge for ancient civilizations and has been solved independently with many solar/lunar calendars, such as the Babylonian, Hebrew, and Chinese lunar calendars, as well as the Hawaiian and Hopi solar lunar calendars, which are described below.

Mesopotamian Calendars

Mathematical advances in Babylonia allowed them to begin to factor and divide large numbers, which in turn allowed them to ascertain whole number multiples of the lunar months and the solar years, such as the 235 lunar month Metonic cycle, which provides a whole number of lunar months (235) and solar years (19), to enable the lunar and solar calendars to match every 6,940 days.

The Babylonians, like many contemporary civilizations, used sets of 12 and 13 lunar month years to reach the 235-month completion of their cycle. These months were named after the various seasons within the Mesopotamian year, and a month began with the visibility of the first crescent moon. A thirteenth intercalary month was added as needed and usually given the name of “second Ululu” or “second Addaru” since it would follow the month of Ululu or Addaru, respectively, to give a complete set of lunar months to a year. Babylonian numbers were written in sexagesimal (base 60) cuneiform, one of the earliest systems of number notation. We still use such sexagesimal numbers in our notation for time (HH:MM:SS), where the colons denote separation between hours, minutes, and seconds.

The Egyptian Calendar

The Egyptian civilization began with a simple calendar based on the 360 + 5 day Egyptian solar year, and three main seasons, named “Inundation,” “Cultivation,” and “Harvest,” divided the year into three parts of 120 days each. Within

the three seasons were 30-day months, each named after Egyptian gods and goddesses. Night and day were each subdivided into 12 equal parts, giving a 24-“hour” day but with hours of different duration depending on the seasons. The word “hour” itself derives from Egyptian timekeeping, since “hour” comes from the Greek word *hora*, which itself derives from the Egyptian word *hor*, which means “day” or “sun’s path” (Lennox-Boyd, 2005, p. 22).

The calendar year had 360 days with a 5-day festival period to honor the chief gods of the Egyptian pantheon (Osiris, Isis, Seth, Nephthys, and Horus). Without any correction, the Egyptian calendar year (365 days) would drift with respect to the actual period of the solar year (365.2422 days), to give complete rotations of the seasons over the course of the thousands of years of the Egyptian civilization. A solution to this problem came from the stars. By watching the morning twilight for the first appearance of the star Sirius (the heliacal rising), the Egyptians noticed that Sirius’ heliacal rising coincided in time with the flooding of the Nile. By AD 144, an additional month of Thoth was added whenever the heliacal rising of Sirius happened within the last 11 days of the last lunar month (Krupp, 1980). The star Sirius, known in Greek as Sothis, was associated with the goddess Isis, and its heliacal rising coincided with the flood of the Nile, and the Egyptian solar calendar was known as the Sothic year.

Egyptian priests noticed the drift of the Sothic calendar over centuries and were able to improve the match between the days of the year with the motions of the stars by means of the decans system. The decans were a group of 36 sets of stars which could be sighted in the early morning twilight in each interval of 10 days known as a decan. In this way, ancient Egypt had two parallel calendars – one ritual calendar of 365 days subject to some drifting and a more accurate star calendar of the decan stars.

For nearly 2,000 years, the Sothic year was the primary calendar of Egypt and much of the ancient world. However, some attempt to fix the drift of the year was made late in the history

of Egypt, in 286 BC, when the Canopus decree of King Ptolemy III added an additional day every fourth year, predating the leap year of the Julian Calendar.

The Ancient Hebrew Calendar

The development of the Hebrew calendar paralleled that of the Babylonian calendar, perhaps due to the Babylonian exile period between 450 and 419 BC. From the first month of Nissannu in the Babylonian calendar (Nisan in Hebrew) to the last of Addaru (Adar in Hebrew), the Hebrew calendar features month names very similar to the Babylonian and, like the Metonic system, inserts extra lunar months over a 19-year cycle. The Jewish calendar is in fact a hybrid of the earlier Canaanite calendar, which started the year closer to the fall equinox, and the Babylonian, which began the year in spring, soon after the Vernal Equinox. This important difference makes the Jewish calendar 6 months out of phase with the Babylonian calendar (Kelley & Milone, 2005, p. 219) (Table 1).

One additional feature shared by the Hebrew and Babylonian calendars is the 7-day week. The book of Genesis includes a description of a 7-day week, with 6 days of labor in which God created the world and a seventh day of rest known as the Sabbath. The word for Sabbath also shares roots in both Babylonian and Hebrew; in Hebrew the word is Shabbat which means “rest,” while in Babylonian the word is sabattu or “seventh.” For the Babylonians, the sabattu, or seventh day, had ominous associations, as were several other days of the lunar month based on both theology and numerology. For this reason, the seventh day was reserved for rites of purification, and this tradition appears to have been shared by the Greeks and Hebrews (Steele, p. 76).

Like many lunar calendars, the Hebrew calendar relies on sightings of a crescent moon to begin the month. Like the earlier Babylonian calendar, it uses a system of 12 and 13 lunar month years alternating in the 19-year cycle (Rich, 2008), with extra intercalary months added as needed to match the solar year.

Calendars and Timekeeping Around the World, Table 1 Babylonian and Hebrew month names. The Hebrew calendar preserves a snapshot of the Mesopotamian calendar of 430 BC, with very similar month names (but shifted by 6 months), and the same Metonic type lunar calendar as the Babylonian system

	Babylonian		Hebrew		Babylonian		Hebrew
1	Nisannu	7	Nisan	7	Tasritu	1	Tishri
2	Ajjaru	8	Iyyar	8	Arahsamnu	2	Chesvan
3	Simanu	9	Sivan	9	Kislimu	3	Kislev
4	Duzu	10	Tammuz	10	Tebetü	4	Tebeth
5	Abu	11	Ab	11	Sabatu	5	Shebat
6	Ululu	12	Elul	12	Addaru	6	Adar

Additional months in the Hebrew calendar are given the name Adar Shenì or Adar Beit and are added to make for 13-month years, a practice which happens seven times in 19 years. Despite the fact that the main features of the calendar were set in place 2,500 years ago, the first year of the Hebrew calendar is set over 5,700 years ago, in the Gregorian year of 3760 BCE, which is thought by some to be the beginning of the universe as described in Genesis. Each year begins with the first of Tishri, which is the festival of Rosh Hashanah (“head of the year”), to commemorate the creation of the universe and to also observe a time at which the Creator judges the universe. Additional holidays include Yom Kippur, the Day of Atonement, on the tenth day of Tishri, and Hanukah, which always occurs on 25 Kislev in the Hebrew calendar, even though its date will shift each year within the Gregorian calendar. Although the New Year (and universe) is recognized to begin on 1 Tishri, the numbers of the Hebrew months begin with Nisan, as does the Babylonian calendar.

The Islamic Calendar

The Islamic world still sets its sacred holidays with a lunar calendar with 12 lunar synodic months of 29 or 30 days, for a total of 354 days. The beginning of a lunar month is set by the first visibility of the crescent moon, giving rise to the crescent moon as the international symbol of Islam. The beginning of the year is known as Al-Hijra and is the first day of the first month known as Muharram. The Islamic calendar begins its count of years in the year when

Mohammed moved from Mecca to Medina and is called the Hijri calendar after this migration, known as the *hijra*. Year 1 of the Islamic calendar corresponds to the day Friday, July 16, 622 CE, making the year 2010 CE in the Gregorian calendar equal to year 1431 AH.

The gap between the Islamic 12 lunar month calendar (354 days) and the solar year (365.25 days) means that the Islamic New Year shifts 11 days earlier each solar year, causing important dates to rotate through the solar year over time. Unlike many other lunar calendars, the Islamic calendar does not allow extra months to reconcile solar and lunar years, since the extra 13th intercalary month is forbidden by the Qur’ān. All of the Islamic holidays will therefore rotate through the solar year. For example, the Islamic New Year dates for 2009 and subsequent years occur on December 18, 2009, December 07, 2010, November 26, 2011, and November 15, 2012, and continue to rotate through the Gregorian solar calendar 11 days earlier each year.

Islamic holidays include the New Year or Al-Hijra and Laylat al-Qadr (The Night of Power), which is believed to be the day when Mohammed first received his revelation that began the Qur’ān. The Qur’ān was revealed to Mohammed during Ramadan, the ninth month of the Islamic calendar, and so the entire month is observed as a month of fasting during daylight hours. The exact date of Laylat al-Qadr varies by country and ranges between the 21st, 23rd, 25th, 27th, and 29th day of the month. During this night, prayers are made and the Qur’ān is studied. The end of the month of fasting occurs on the first day of the following month of Shawwal and is the holiday known as Eid al-Fitr, celebrated by communal

Calendars and Timekeeping Around the World, Table 2 Major Islamic holidays and their significance along with the Gregorian date in 2010 (later years have dates 11 days earlier each year)

Holiday	Date in Islamic calendar	Meaning	Gregorian date in 2010/2011
Al-Hijra	1 Muharram	Date of Mohammed's migration to Mecca (Hijra)	December 07, 2010
Isra al-Miraj	27 Rajab (7th month)	Ascent of the Prophet Mohammed	June 28, 2011
Ramadan	1 Ramadan (9th month)	Month during which Mohammed received revelation of the Quran	August 01, 2011
Laylat al-Qadr	21–29 Ramadan (varies by country)	"Night of Power" – date when Mohammed received first revelation	August 26, 2011
Eid al-Fitr	1 Shawwal (10th month)	"Breaking of Fasting" and end of the month of Ramadan	August 30, 2011
Eid al-Adha	10 Dhu'l-Hijjah (12th month)	Date of Ibrahim's willingness to sacrifice Isma'il; end of Hajj	November 06, 2011

prayers followed by extensive family gatherings and feasting along with an exchange of gifts.

Other important holidays include Isra al-Mi'raj, which celebrates the Ascent of the Prophet Mohammed and occurs on the 27th day of the seventh month of Rajab, and the Eid al-Adha, which is approximately 70 days after the end of Ramadan, on the 10th day of the 12th month of Dhu'l-Hijjah. The Eid al-Adha is a time of prayer and sacrifice of a lamb or other animal, often a goat, and celebrates the willingness of Ibrahim (Abraham) to sacrifice his son Isma'il. This holiday occurs at the end of the hajj (the pilgrimage to Mecca). A summary of the Islamic holidays with their dates and meanings is given below in Table 2.

The Hawaiian Calendar

The ancient Hawaiians developed an original lunar calendar that made use of the lunar months and the position of the Pleiades star cluster to create a stellar-lunar calendar. The year was known as the *makahiki*, and it was divided into two equal sections for summer and winter. The key for maintaining accuracy of the lunar calendar was the synching effect of the Pleiades star cluster, known to the native Hawaiians as *Makali'i* (Johnson & Mahelona, 1975).

The beginning of the first Hawaiian season and the Hawaiian year is in late October or November

and is marked by the rising of the Pleiades in the east just after sunset, known as *makali'i-hiki*. The first month begins when the crescent moon is first sighted in the evening (the day known as *hilo*), and sets of 30 nights are counted from this point. Each night had particular associations with agriculture (planting of certain crops were best on particular nights) and religion (including worship of specific gods during the *tabu* or holy nights). The second season of summer began in May when the Pleiades were first sighted in the predawn sky (during their heliacal rising). The twelve 30-day lunar months of the Hawaiian calendar, with their 30 named nights, kept track of the year, but occasionally some months would need to be added to reconcile the annual cycle of the Pleiades with the lunar calendar, much as in other lunar calendars.

By coincidence, Captain Cook's final landing in Hawaii in February 1779 came just after the Hawaiian New Year period, and the Hawaiians may have interpreted Cook's arrival to be an inauspicious premature return of the god Lono, which required a ritual sacrifice to return order to the universe (Ruggles, 2005, p. 179).

The Zuni Calendar

The Zuni observed both solar and lunar calendars. Within the culture is the Sayatasha's Night Chant, in which an actor portraying the masked god Sayatasha keeps track of the days and

months. The actor plants prayer sticks every full moon throughout the year until October for 10 lunar months. After the tenth month, he begins counting the days before the beginning of an intense end of year dance known as *Shalako*, by untying a string which contains 49 knots, 1 for each day. At the end of 48 days, Shayatasa's actor begins the long talk, and he and a set of other masked gods (the *kachinas*) participate in the *Shalako* dance until dawn. During the final night, the actor recites the precise poem intoned by hundreds of generations of past Sayatasha impersonators, reciting word for word a Night Chant which describes the motions of the sun and moon, the rituals of the people, and their origins.

The Inuit Calendar

The Inuit developed a set of seasonal star markers for measuring the duration of the long winter night, which can last for months. The stars Altair and Tarazed formed the Inuit constellation known as *Aagjuuk*, and these two stars first became visible in late spring and were used to indicate the end of the long winter night. The two top stars of Orion's "shoulders," Betelgeuse and Bellatrix, were known as *Akuttujuuk* and were used to mark the middle of the winter, known to the Inuit as the "dark period." The Pleiades were used to mark time by many different Arctic groups and had the name *Sakiattiak* among the Igloolik, who also used them for navigation. The bright star Arcturus, known to the Inuit as *Sivullik*, or "leader," is visible in the evening sky, being the first star (or leader) to be sighted in the early evening in the west. For the Inuit of Coronation Gulf, Canada, the transit of Arcturus signaled the beginning of the sealing season (MacDonald, Royal Ontario Museum, et al., 1998, p. 78). The Inuit observed a set of 13 lunar months, and a simple system was used to determine whether a year had 12 or 13 lunar months. If the winter solstice coincided with the first day of the thirteenth month, it was skipped, giving a natural alternating pattern of 12 and 13 lunar months over the years.

The Greek Calendar

The early Greek calendar is described in the "works" section of Hesiod's *Works and Days*, one of the earliest surviving works of Greek culture. Celestial observations included noting the heliacal rising of stars and star clusters such as the Pleiades. The Greek year began in October and continued on through September. The Greek days were numbered from 1 to 30, like the Hawaiian month, and included auspicious days for various activities such as "bringing brides home," "giving birth to boys," "planting," "shearing," and "worshipping gods." The days were set by the phase of the moon, with the month beginning at the first sighting of the crescent moon.

Each of the different Greek city-states had different month names, and separate priests would call the beginning of the lunar month and decide when an extra month was needed based on stellar observations. Year names were set relative to the reign of a particular ruler or relative to key events in local history. One technique used to provide a common reference for year names was the Olympic Games, which all of Greece would recognize and which began in the year 776 BC. Any confusion about the Olympic Game number was fixed by attaching to the date the name of the champion of the most prestigious Olympic event, the footrace known as the *stadium*.

The Roman Calendar

The Roman calendar began before the first glimmerings of the Roman Empire, back on the date of January 1, 4713 BC, which sets the origin of the Julian Day count. The Julian Day is still used in astronomy research where the complexities of orbital periods require the use of a uniform count of days. The origins of Roman timekeeping began not in 4713 BC, but in the period of the Roman monarchy, from approximately 776 BC to 509 BC, when the Roman calendar had ten named lunar months. Each lunar month was divided into named days; the "calends" were the first days of the month, the nones were the 5th days of the

month, and the Ides (Idus) were the 13th day of the month.

The “calends” marked the beginning of both the lunar month and a business cycle, in which debts were to be paid at the beginning of the month, before the “nones,” with the ides marking the middle of the lunar month. The calendar at first counted only those days when business was being done and featured a 10-month year which started at the vernal equinox. The last of the month names (unchanged to this day) were simply their numerical place in Latin corresponding to “fifth” (Quintilis), “sixth” (Sextilis), “seventh” (September), etc. The months in the Roman Republic were of unequal length – Martius, Maius, Quintilis, and October were all of 31 days, and Aprilis, Iunius, Sextilis, September, November, and December were each of 29 days. After the end of the business and agricultural year, near the winter solstice, the early Romans simply stopped counting the days of the year until the month of the vernal equinox, which would signal the beginning of the New Year.

In order to have a complete annual calendar, the Romans later added two additional months (Januarius, with 29 days, and Februarius, with 28 days) in 509 BC to cover the solar year, adding up to 355 days with 12 lunar months. In order for the solar and lunar years to match evenly, the irregular lengths of the lunar months were supplemented with an intercalary month roughly every other year.

Julius Caesar, as part of his duties as emperor and chief pontiff of Rome, discarded the old lunar calendar in 46 BC. To reform the calendar, Caesar added 10 days to the year by lengthening the five shorter 29-day months by 2 extra days, with the exception of February, which was kept at 28 days with an extra “leap day” added every 4 years. By the time of Caesar’s reforms, the calendar had drifted by over 80 days, and so the year 46 BC is known as the “year of confusion” (*annus confusionis*) since it was 445 days long! The result of Caesar’s reforms was the Julian calendar, which includes 365 days, with an extra 0.25 days from leap years to give an average solar year of 365.25 days (Steel, 2000). The Julian calendar, with 365.25 days, provides a close

match with the length of the solar year of 365.2422 days. Caesar’s calendar remained in place for over 1,000 years.

The Julian calendar is still in use today, with the (minor) correction known as the Gregorian reform of 1582 (named after Pope Gregory XIII), which took back 3 of the leap years in centuries not divisible by 4 (1700, 1800, 1900), while retaining leap year in those divisible by 4 (2000, 2400, etc.). The result of the Gregorian reform is to set our modern calendar to have a year of 365.2425 days, which gives an error or “drift” of only 0.0001 days in a year.

The Incan Sidereal Year

For the Inca, time was measured in many ways, from the natural cues of the environment, from the Moon and Milky Way, and from the sightings of stars, planets, and the Pleiades in the night sky.

The motions of the Milky Way in the night sky from 1 month to the next also served as a large “hour hand” of night and provided a similar splitting of the year into four parts. The Inca calendar was also set by heliacal risings of bright stars, star clusters, and dark cloud constellations. The heliacal rising of the brightest star in the Southern Cross (α Cru), associated with *Yutu*, a bird and dark cloud constellation) marked the beginning of the agricultural season, while the rising and superior culmination of the stars α - and β -Centauri (associated with the “eyes of the Llama”) coincided with the birth and mating season of the llama. The positions of star clusters were noted both above in the night sky (at zenith or transit) and below under the feet and crops of the Inca (at nadir or inferior culmination). For example, the appearance of the Pleiades or *collca* at nadir, directly beneath the earth, was thought to be a harbinger of the best time for planting (Urton, 1981).

The Inca religion made use of worship sites rotated through the city to various shrines or *huacas* on a daily cycle, arranged along patterns of space that connected the shrines to the horizon and the stars beyond. The ritual calendar linked

all of the 328 *huacas*, one for each of the named days in the 328-day Inca year.

The somewhat unusual number of days in the Inca year comes from the observation of the Incan lunar month, which is based on a unique lunar/stellar calendar. The 27.3 day Incan month was based on the 27.3-day sidereal period for the moon to return to the same position against the stars, as opposed to the more familiar 29.5-day lunar synodic month of most other cultures. The Inca would carefully watch the location of the moon in the sky relative to the stars to determine the beginning and ending of lunar months. Groups of 12 lunar sidereal months combined to create an Incan year of 328 days, giving the annual calendar, but also leaving behind a group of 37 days which were uncounted (Aveni, 1997).

Calendars of Ancient India

Another culture that made use of the moon's position relative to the stars was ancient India, where the practice of Hindu astrology required the use of moon and star coincidences known as *nakṣatras*. Like the Inca, the early Hindu astrologers would watch the position of the moon against the background of a set of indicator stars, which set the lunar sidereal calendar. For determining auspicious dates of weddings and births, the Hindu astrologer would combine the lunar phase of the date with the lunar sidereal location or *nakṣatra* to get a more precise reading of the sky.

The *nakṣatra* system dates to before 1000 BC, in the era of the *R̥gveda*, a collection of Vedic Sanskrit hymns. A set of 27 stars were chosen near the ecliptic plane as references for gauging the position of the moon as it moves through its 27.3-day lunar sidereal cycle. The stars, their corresponding names in Hindu and European astronomy, and the corresponding constellations are presented below in Table 3.

The Hindu astronomers divided the ecliptic into 27 *nakṣatras* and also divided the sky during any individual day into 27 parts, known as *yogas*. The *yogas* (analogous to hours) were based on the

angular distance along the ecliptic of the sun and moon, which set a reference point on the sky, and from this point divided the sky into 27 regions 13.333° wide. Additional terms and concepts of interest to the Indian astronomers and astrologers include the *tithi*, which is defined as the angular distance between the Sun and moon (something akin to lunar phase), and the *karaṇa*, the time required for the distance between the sun and moon to increase by a distance of half of a *tithi*.

The Hindu solar calendar functioned much like many other calendars, with a New Year beginning with the first lunation after the Vernal Equinox, in April. A set of 12 solar months, or *rashi*, was observed based on the sun's position within the ecliptic. Each of the 12 named solar months included 1 of the 12 named lunar months. The named lunar months include (in order): Chaitra, Vaishākh, Jyāishtha, Āshādhā, Shrāvana, Bhādrapad, Āshwin, Kārtik, Mārgashīrsha Paush, Māgh, and Phālgun. Each lunar month is matched with a solar month, and lunar events determine any corresponding festivals within that month. For example, when the sun is Capricorn, during January, it is the tenth solar month (*rashi*), known as Makar, and the lunar month is known as Paush. A festival (or *mela* in Bengali) in this month in the province would be known as *paush mela*. A summary of the month names within the Indian calendar is shown in below in Table 4.

The Hindu calendar, like many ancient calendars, included a 7-day week. Days of the 7-day week in the Hindu calendar, known as the *vaasara* in Sanskrit, are named after the 7 celestial bodies known to the ancients, in the same order as in the Western calendar. The sequence of days (in order) includes days named after the Sun, Moon, Mars, Mercury, Jupiter, Venus, and Saturn, which in Sanskrit are Ravi, Soma, Mangala, Budha, Guru, Shukra, and Shani, respectively. Therefore the Indian day names are Ravi vasara (Sunday), Soma vasara (Monday), Mangala vasara (Tuesday), Budha vasara (Wednesday), Guru vasara (Thursday), Shukra vasara (Friday), and Shani vasara (Saturday).

Since India as a modern country is very diverse, with 22 officially recognized languages,

Calendars and Timekeeping Around the World, Table 3 Hindu nakṣatras, used to mark the path of the moon through the stars during the 27.3-day lunar sidereal month (Ojha, 1996)

Nakshatra	Location on sky	Shape	Stars
1. Ashwini	and γ Arietis (head of Aries)	Face of horse	3
2. Bharani	35, 39, and 41 Arietis	Yoni	3
3. Krittika	Pleiades + Alcyone	Curved knife	6
4. Rohini	Aldebaran	Cart	5
5. Mrigashira	λ and ρ Orionis	Face of deer	3
6. Ardra	Betelgeuse	Jewel	1
7. Punarvasu	Castor and pollux	House	4
8. Pushya	γ, δ , and τ Cancrui	Arrow	3
9. Ashlesha	δ, ϵ, η , and σ – Hydrae	Circular	5
10. Magha	Regulus	House	5
11. Poorva-phalguni	δ and τ Leonis	Manchaka	2
12. Uttara-phalguni	Denebola	Small cot	2
13. Hasta	Spica	Hand	5
14. Chitra	α to ϵ Corvi	Pearl	1
15. Swati	Arcturus	Coral	1
16. Vishakha	α, β, γ , and ι Librae	Torana	4
17. Anuradha	β, δ , and π Scorpui	Vali	4
18. Jyeshtha	α, σ , and π Antares	Circular earring	4
19. Moola	$\epsilon, \zeta, \eta, \tau, \iota, \kappa, \lambda$ Sco (tail and stinger of Scorpius)	Tail of a lion	3
20. Poorva-shadha	δ and ϵ Sagittari	Tusk of an elephant	11
21. Uttarashadha	ζ and σ Sagittari	Manchaka	2
22. Shravana	α, β , and γ , Aquilae (Altair)	Aeroplane (??)	3
23. Dhanishta	Delphinus	Mridanga	4
24. Shatabhisha	γ Aquarii	Elliptic	100
25. Poorva-bhadra	α and β Pegasi (Markeb)	Manchaka	2
26. Uttara-bhadra	γ Pegasi and α Andromedae	Twins	2
27. Revati	ζ Piscium	Mardala	32

and over a dozen separate historic cultures within its borders, there is a good deal of variation in the names of months, days, and timing of festivals that reflects the linguistic and religious diversity of the country. The effects of precession are causing many of the ritual holidays of India to lose their astronomical underpinnings, such as coincidence with solstice or equinox dates (Aslaksen and Rugulagedda 2001; Nath, 2008).

In the Hindu cosmology, time unfolded in a set of four ages, in a descent from pure order into decay, before destruction and renewal. The first of these ages was known as *kritya* or *satya* and was symbolized by the bull of creation on all four legs. This first age lasted 4800 “divine years,” which corresponded to 1,728,000 of our “human years.” During this first age, the universe was in a state of purity, and the laws of dharma, rules

that are in accord with order, were obeyed. The second age was known as *treta*, and in this age of 3,600 divine years (1,296,000 human years), the first hints of decay are visible, and the cosmic bull is symbolized to have only three legs. The third age was known as *Dvapara* and lasted 2,400 divine years (864,000 human years), and the fourth and final age was the age of *Kali*, which lasted for 1,200 divine years (432,000 human years). After these four ages were complete, there would be a short period of twilight known as *sandhya*, or *sandhyamasha*, before the age would be complete, and a cycle of destruction and recreation would bring the universe back into its pure *kritya* state (Dallapiccola, 2003).

The enormous grouping of this vast expanse of time in the four ages comprised the length of time known as the *mahāyuga*, or “great cycle.” Each

Calendars and Timekeeping Around the World, Table 4 The Hindu and traditional Indian calendar included both solar months and lunar months (source: <http://www.nationmaster.com/encyclopedia/Hindu-calendar#tithi>)

Solar months	Season	Gregorian months	Zodiac
Mesh	Vasant	April/May	Aries
Vrushabh	(Spring)	May/June	Taurus
Mithun	Grishma	June/July	Gemini
Kark	(Summer)	July/August	Cancer
Simha	Varsha	August/September	Leo
Kanya	(Monsoon)	September/October	Virgo
Tula	Sharad	October/November	Libra
Vrishchik	(Autumn)	November/December	Scorpius
Dhanu	Hemant	December/January	Sagittarius
Makar	(Autumn-winter)	January/February	Capricornus
Kumbha	Shishir	February/March	Aquarius
Meen	(Winter-spring)	March/April	Pisces

grouping of four ages amounted to approximately 4,320,000 years and comprised a brief segment of a dream within the sleep of Brahma. One thousand of these cycles created a length of time known as the *kalpa*, which amounts to about 4.3 billion years, close to the current scientific estimate of the age of the earth, the sun and the solar system. This enormous expanse of time was also imagined to be the length of one full day in the life of Brahma.

Chinese Calendars

The Chinese recognized a set of five elements that describe all earthly and celestial phenomena. The five named elements included wood, fire, earth, metal, and water, which had celestial counterparts in the planets Jupiter, Mars, Saturn, Venus, and Mercury, respectively. The solar year was also divided into five seasons, one for each element. The cycles of time and motions of the heavenly objects tied into these numbered elements and connected the essence of these elements to life on earth. Motions of the planets and appearances of “guest stars” and “sweepers” (now known as supernovae and comets) gave a picture of the universe that reflected the heavenly mandate of the emperor on earth.

The Chinese also divided space into systems that included 4, 10, 12, and 28 parts, which arose from both ancient folk traditions and Chinese

philosophy developed over thousands of years. The ancient Chinese believed that each of the four cardinal directions had a symbolic animal and color, much like many Native American peoples.

The Chinese animals and colors include the Black Warrior/Tortoise for North, the Red Bird for South, the Blue Dragon for East, and the White Tiger for West. Early Shang writings refer to “Ten Heavenly Stems” and “Twelve Earthly Branches,” a set of reference stars set the calendar, and the planet Jupiter, respectively. The Heavenly Stems provided a system similar to the decan stars of the Egyptians and helped synchronize the calendar with the seasons. The Earthly Branches were a timekeeping system in which the 24-h day (and the sky) was divided into twelve segments, named after animals from an earlier folk tradition. The motions of the planet Jupiter would circle the sky in a 12-year cycle, the basis of the Chinese Zodiac which assigns 1 of the 12 Earthly Branches (rat, bull, tiger, hare, dragon, serpent, horse, sheep, monkey, rooster, dog, and pig) to each year as Jupiter moves through its 12-year synodic period. The 28 *xiu* or lunar mansions also helped set the Chinese calendar, as they could be observed at dawn or sunset to help set the calendar.

Professional Chinese astronomical records cover over 1,600 years of observations, from approximately 200 BC to 1400 AD and provide rich material for dating ancient astronomical

events. Below are samples of Chinese observations of ancient supernovae, translated from the original records:

“A star appeared to the south of the Ti lunar mansion, east of Ku-Lou and west of Chi-Kuan. At one time it resembled the half moon, shown with pointed rays, and was so bright that objects could be seen by its light” (description of the Supernova of 1006)

“..it was visible by day, like Venus; pointed rays show out from it on all sides; the color was reddish-white. Altogether it was visible in the daytime for 23 days” (description of the Crab Supernova of 1054)

“The star was as big as a peach. . . .” (description of Supernova of 902 AD, which was also visible for a year).

(Kiang, 1969; Shen, 1969)

Maya Timekeeping and Calendars

The interlocking calendars of the Maya contained two short-term calendars, the *tzolkin* and the *haab*, which were based on a 260-day cycle of 13×20 day months, and a $360 + 5$ -day cycle of 12×30 day months. In addition to these two calendars, the Maya kept track of cycles of much larger eras or eons of time, by bundling the days into groups of 20 and 13, into what we would call centuries, millennia, and 10,000-year periods, which the Maya called tuns, katuns, and baktuns.

The Mayan number system was developed to keep track of extremely large numbers from timekeeping and is unique in two aspects: (1) the use of a base-20 number system (common to Mesoamerican people, but perhaps invented by the Maya) and (2) the development, independent of Indian and Arabian mathematicians, of the number zero.

Examples of Mayan numerals are given below and are part of a base-20 number system, as opposed to our base-10 number system (Fig. 1).

By grouping days into bundles of 20 named days, the Maya formed the basis of the “week” in their calendar, which when combined with 13 sacred numbers made a 260-day cycle known as the *tzolkin*. The word *tzolkin* or *tzolk’in* means “count of days” in Yukatek Maya and was the fundamental basis for the Mayan calendar. Each

of 20 named days rounding through a cycle with 13 numbers made a cycle known as the *uinal*, or a Mayan week, in which 20 days were grouped. Each day name would be paired with a number, until the *uinal* was complete. The pairings would continue until every possible pairing of 20-day names and 13 numbers had been made, after 260 days.

The combination of 20-day names and 13 numbers provided the fundamental cycle of time for the Maya. Some have likened the process of pairing names and numbers to interlocking wheels; one wheel would have 13 numbers and would rotate next to a wheel with 20 names. The imaginary assemblage would continue rotating until all 260 pairs had been made.

A period of 260 days does not easily match with lunar months, the solar year, or even the motions of Jupiter. However, many authors have noted that 260 days is roughly half the period of the Venus year – the time Venus spends within either the Eastern or Western sky before disappearing in the glare of the sun. The period between maximum elongations of Venus is 584 days, which divides into two 260-day periods for visibility and two 32-day periods in which Venus crosses either behind or in front of the sun.

Since the Maya needed to maintain crops and time their activities with the stars, a second calendar was needed to fix dates within the solar year. The official count of solar days for the Maya was known as the *haab*, or “vague year,” and took secondary importance to the *tzolkin*. The *haab* operated much like the *tzolkin* but had its basis in 18 named months, with 20 numbered days, and operated somewhat more simply, with its names consisting of 1 of 18 month names, and 20 numbers, progressing along with day names such as “1 Pop,” “2 Pop,” “3 Pop,” etc., until 20 was reached, and then the next month would be used. The 18 named months and 20 numbered days together gave a 360-day period, close to the solar year, known as the *tun*. To keep the calendar from drifting, an extra unnamed (and very unlucky) 5 days were added to the end. The year-ending days were known as the *uayeb* to give a 365-day solar year, much as in the early Egyptian calendar, except the *uayeb* was a time of

0	1	2	3	4	15	16	17	18	19
									
5	6	7	8	9	20	21	22	23	24
									
10	11	12	13	14	25	26	27	28	29
									

Calendars and Timekeeping Around the World, Fig. 1 Examples of Mayan base 20 (or vigesimal) numerals, showing their representation of zero (developed independently from Indian and Arabian mathematicians) and counting with groups of *dots* and *bars*

representing ones and fives, respectively, until reaching 20, the base number for their number system (Source: <http://commons.wikimedia.org/wiki/Image:Maya.jpg>)

dread instead of a time of festivities. Groups of 20 of the haab years formed the grouping known as the *baktun*, which is analogous to a Mayan decade.

The Calendar Round

The combination of a tzolkin date and a haab date gives a unique number name combination that uniquely specified a day within the Mayan calendar cycle. Some basic mathematics will show that the two cycles will both repeat after $73 \times 260 = 18,980$ or $4 \times 13 \times 365 = 18,980$ days, which corresponds to about 52 solar years. The pairing of these two cycles forms the basis of the shortest and most profound of the Mayan cycles of creation and destruction, the Calendar Round. The intermeshing of these two calendars can also be visualized as a set of two imaginary wheels, and when both wheels have turned through all combinations of tzolkin and haab names (after 18,980 days or 52 years), the calendar round would be complete.

The year bearers for the Maya were the days *Kan*, *Muluc*, *Ix*, and **Caucac**, associated with the Chac Gods in the four cardinal directions of East, North, West, and South. The four different types of years required four different New Year ceremonies, soon after the Winter Solstice. During a New Year ceremony, offerings of corn and sacrificial animals would be made, and

a procession would bring a large number of people into town through the appropriate cardinal direction (Sharer & Traxler, 2006, p. 550). Most dreaded were the *Caucac* years, which were associated with dreadful calamities such as swarms of killer ants or flocks of crop-destroying birds. For these years more elaborate ceremonies were performed.

After the completion of the 52-year cycle, the Aztec New Fire Ceremony included observations of the Pleiades to see if it stopped its motion in the middle of the night, signifying the end of the present world. Upon observing that the Pleiades were not frozen on the sky, fires were lit, and chants were sung to help renew the world and preserve order in the cycles of the heavens. The presence of fires atop the mountains could be seen far away, signaling the renewal of a new cycle to the villages below.

Larger groupings of time, analogous to our centuries and millennia, were also of great interest to the Maya. The first of these is the *katun*, mentioned earlier, which is a group of 20 tuns, which amounts to 7,200 kins, or about 20 years or 7,200 days. Of particular interest to the Maya was the ending of each *katun* or 7,200-day period. Mayan monuments provide excellent records of the Mayan kings during the Classic and Late Classic periods and include long count dates (Sharer & Traxler, 2006, p. 546).

Groupings of 20 *katuns* form a *baktun*, which is 144,000 days, or about 394 years. These very

long groupings of days form the basis of a Mayan long count date, which would record in each digit the number of *baktuns*, *katuns*, *uinals*, and days since the beginning of the current age within the long count. By adding together all of the numbers and the corresponding bundles of days, it is possible to place a date exactly relative to the beginning of the current age. A long count date would be completed by including the *tzolkin* and *haab* designation for the date at the end.

As an example, to specify a long count date, one might see the following numbers and names:

9.15.10.0.10 3 Ahau 3 Mol

The long count date specifies in its five (base 20) digits the number of days since the beginning of the current age. The example above would include (starting from the left, which counts the largest grouping of days):

$$9 \times 20 \times 18 \times 20 \times 20 + 15 \times 20 \times 18 \times 20 + 10 \times 20 \times 18 + 0 \times 20 + 10 \text{ days} = 1,407,610 \text{ days}$$

For this example, as we add up the days we include 9 *baktuns* (1,296,000 days) + 15 *katuns* (108,000 days) + 10 *tuns* (3,600 days) + 10 *kin* (10 days) which places the Mayan long count date 9.15.10.0.10 1,407,610 days from the beginning of the universe.

The date also corresponds to a unique date in the two *tzolkin* calendars and can be tied to our Gregorian calendar. For our example, the long count date above, 9.15.10.0.10, is named 3 *Ahau* 3 *Mol* in the Mayan calendar, or June 30, AD 741, in the Gregorian calendar (Sharer, p. 574).

The beginning of the universe, which forms the origin of the Mayan time-based cosmology, corresponds to the Gregorian date of 13 August 3114 BC. On the first day of the age, we would have the long count date of:

0.0.0.0.0. with Mayan day names 4 Ahau 8 Cumku = 13 August 3114 BC

The very ancient date of 3114 BC predates the Mayan civilization, since the oldest known long

count date from Mayan archaeology is from Stela 2 at Chiapa de Corzo, which is listed as approximately 114 BC. Presumably, the beginning of the calendar in August of 3114 BC is simply a result of numerology and mathematics, much like the beginning of many other calendars we have seen. Other calendars with such beginning dates include the Julian dates, which begin in 4713 BC, the Jewish calendar, which begins in 3761 BC, the ancient Greek Olympiad-based calendar, which placed the first Olympics in 776 BC, and the Greek Orthodox calendar, which begins in 5509 BC (Sharer & Traxler, 2006, p. 568).

The last date of the current age is when the leftmost zero (the *baktun* indicator) goes from 12 to 13, which corresponds to the last day of the current age

$$12.19.17.19.19 \rightarrow 13.0.0.0.0 = 23 \text{ December, } 2012 \text{ AD}$$

The time between these dates, which would be the duration of the age we live in, is 13 *baktuns*, 1,872,000 days or 5,200 years! The Mayan astrologers would expect that at this date we would have a complete renewal (and destruction) of our world, but also with the expectation that life and time would begin again, in an endless cycle of recurrent events.

The Long Count and Cycles of the Universe

The largest cycles of days for the Maya come into play in the form of the long count described above, which describes ages of 5,200 years. However in some contexts (such as in monumental carved stoned stelae), long count dates would be specified in an even longer format, with two additional digits beyond the usual five places of the long count. Below is an example.

13.13.13.3.11.8.0.19 5 Imix 9 Kanka

These additional digits refer to even longer units of time, which would be groups of 20×400 years (a *pictun*), $20 \times 20 \times 400$ years

(a *calabtun*), $20 \times 20 \times 20 \times 400$ years (a *kinchiltun*), and $20 \times 20 \times 20 \times 20 \times 400$ years (an *alautun*), corresponding to cycles of 8,000; 160,000; 3,200,000; and 64,000,000 of the Mayan *tuns*. The number of solar years within each of these units of time is slightly less than the number of *tuns*, since a *tun* is 360 days, and the solar year is 365.2422 days. The largest of these time units recognized by the Maya is the *alautun*, which corresponds to about 63,000,000 solar years, or 23 billion days!

To summarize the complete set of Mayan time units we provide the following listing of the many units within their reckoning of time below. Each line in the summary below corresponds to one position in a long count date.

Summary of Mayan units of time
1 kin or 1 day
20 kins = 1 uinal or 20 days
18 uinals = 1 tun or 360 days or ~ 1 solar year
20 tuns = 1 katun or 7,200 days ~ 19.7 solar years
20 katuns = 1 baktun or 144,000 days = 400 tuns ~ 394.24 solar years
20 baktuns = 1 pictun or 2,880,000 days = 8,000 tuns ~ 7885.25 solar years
20 pictuns = 1 calabtun or 57,600,000 days = 160,000 tuns $\sim 157,703$ solar years
20 calabtuns = 1 kinchiltun or 1,152,000,000 days = 3,200,000 tuns $\sim 3,154,000$ solar years
20 kinchiltuns = 1 alautun or 23,040,000,000 days = 64,000,000 tuns $\sim 63,000,000$ solar years

(Sharer & Traxler, 2006)

Calendars in East Asia

Nakayama Shigeru

Successive attempts to improve a typical luni-solar calendrical system for reconciling two fundamentally incommensurable periods – the tropical year and the synodic month – were made throughout

the history of Chinese and Japanese calendars until their replacement by the Gregorian solar calendar in modern times, the Japanese in 1883 and the Chinese in 1912.

The length of a synodic month varies between 29.0 and 30.1 days. The luni-solar calendar provided for “short” months of 29 days and “long” months of 30 days. Calendrical scientists attempted to arrange short and long months so that the moon’s conjunction would take place on the first day of every month. The day notation of the lunar month represented the phase of the moon; for instance, the 15th day of the month was always a full moon, while the 1st day was a new moon.

In addition, the Chinese had an independent system of solar intervals (*qi*) for indicating seasonal changes, the most important phenomena in the regulation of agriculture. The tropical year was divided into 12 equal intervals of time, the element of a purely solar calendar. The middle point of each interval was called its *zhongqi* or interval center. The synodic month was always slightly shorter than an equal interval, and thus an interval center did not occur in certain months. Such months were designated as intercalary months, and in this way the sequence of synodic months was reconciled with the seasons of the tropical year. The year that included an intercalary month had 30 synodic months. This occurred roughly once every 3 years.

The Chinese calendar calculators were, however, not satisfied with providing a conventional calendar, in which the courses of the sun and moon were reconciled, merely for civil use; they also tried to include the anomalistic motions of the sun and moon.

Prior to the Tang period (roughly seventh to ninth centuries), a mean synodic month of approximately 29.5306 days was used for this purpose. Shortly before the Tang, however, a proposal was made to take anomalistic motions of the sun and moon into consideration in calendar making. Liu Zhuo (AD 544–610) used the term *dingshuo* (true synodic month) as opposed to the older concept of *pingshuo*

(mean synodic month). During the Tang period the idea of the true synodic month was adopted in the official calendar in order to attain better agreement with the actual phases of the moon, and also for convenience in eclipse-prediction calculations.

Liu Zhuo also made the first recorded distinction between *dingqi* and *pingqi*. The former is the period of time for the sun to move through a 30° angle of the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course), which therefore varies in length in accordance with the anomalistic movement of the sun. The latter is the average length of time to move through a 30° angle. This concept, *dingqi*, however, was not actually adopted in the official calendar until the Qing period (the seventeenth century on).

Daily life is never affected by such small discrepancies in the calendar as those due to the anomalistic motions of the sun and moon. The astronomical attainments of the Chinese calendrical schemes went far beyond the concern of the common people. They included not only luni-solar phenomena but also the periodic motions of the five planets. They were called *li*, which corresponds to “ephemeris” as well as “calendar” in the narrow sense.

In the case of the Julian calendar reform data were doubtless gathered from prior calendars and not from actual observations. One recalls in this connection Lilius’ effort in the Gregorian calendar reform to reduce the toil of observation and computation so as to provide an artificial system independent of astronomical tables and indeed of any link with actual celestial phenomena. The Western calendar was not, in terms of astronomical precision, overwhelmingly rigorous.

The difference of purpose between calendar-making in the West and East is clear. Whereas the Western calendar was divorced from the development of astronomical science, and aimed at schematic convenience for civil and religious proposes, the East Asian calendar, disregarding civil convenience, was an attempt to represent

faithfully the movements of the heavenly bodies. It thus became much more complicated than its practical applications warranted. A sharp separation of scientific astronomy and civil calendar-making did not take place in traditional East Asia. Its scope was confined to the composition of a luni-solar ephemeris which stood or fell on the accuracy with which it could predict eclipses, which is the best way to check the validity of any luni-solar calendar. Analysis of planetary motions was rather ancillary to the main stream of Chinese calendar making.

Cosmological discussions often took place during the Han and Six Dynasties periods (second century BCE to sixth century AD), although they were discontinued soon after. In the Tang period the Chinese astronomers were no longer interested in this particular speculative pursuit. While occasional cosmological debates were found among philosophers, scientific cosmology was long set aside and forgotten in professional calendrical science circles until the time of the Jesuits' impact in the seventeenth century.

Perhaps the most striking thing about the recastings of the civil calendar in China was their frequency. In 2,000 years there were more than 50 revisions of the Chinese calendar, and then of the Japanese calendar, whereas in the West there was only one major reform, the Gregorian. Why were the Chinese so preoccupied with the calendar that they were driven to such repeated efforts? There were two major reasons, one political and the other technical.

Among the ancient Chinese the idea prevailed that a ruler received his mandate from heaven. In the early period, therefore, after important changes within individual reigns and always after important changes of dynasty, the new emperor was prompted to reform key institutions, especially the official calendar, in order to confirm the establishment of a "new order" which a new mandate implied. A new mandate meant a new disposition of celestial influences. The Han Emperor Wu (r. 1480–1487 BCE) was advised by his councilor to revise the calendar and change

the color of ceremonial vestments, in order to make it clear that his rule was based on a true mandate. The result was the imperial edict by which the *Taichu* calendar was adopted.

This notion was responsible for the subsequent course of development of Chinese calendrical science. Calendrical science enjoyed governmental sponsorship throughout its history, and had more prestige than other branches of science; it was China's most genuine contribution to the exact sciences. The history of Chinese and traditional East Asian astronomy is, for the most part, the history of calendar-calculations.

In the course of time, however, the political importance of calendar reform dwindled. The restriction of calendar reform to change of dynasty was not strictly observed by the Northern Wei (fifth century AD) and succeeding northern dynasties. Some rulers unduly took advantage of calendar reform to gain or regain popular support. The calendrical significance and authority of calendar revision were thus largely lost. In the Tang dynasty, the motive for calendar reform became simply to correct disagreements of the calendar with observed celestial phenomena. Hence, reforms were carried out whenever a small error was found. This accounts for the frequent revisions in later phases.

Beyond the concern with timekeeping, the Chinese astronomers dealt mainly with apparent solar and lunar movements and eclipse prediction. The Chinese luni-solar calendar required revision whenever the discrepancy between calculation and observation became noticeable. For this purpose, the government founded the Office of Astronomy, and incumbent astronomers were responsible for the improvement of the calendar. The government enjoyed a monopoly on the regulation of time, which contributed to imperial control of daily life and which strengthened the central power and prestige at a sacrifice of civil convenience. People were forced, in matters of everyday life, to follow a calendar based on a complicated, "astronomically rigorous" and "state-authorized" ephemeris, which, unlike our

solar calendar, could never be prepared by laymen, but depended on the skill of official astronomers.

Despite early recognition that a single perpetually valid calendrical scheme was impossible, the calendar calculators never tired of proposing revisions. Their incentive must be ultimately attributed to the rational desire to conform to the celestial order, a philosophical compulsion to accept the phenomena of the material sky as the most authentic reality. It was because of this orientation that calendar-making maintained its status as an integral part of Chinese science and learning for such a long time.

Modernization and Westernization

As the official calendar was quite an important part of the social system, westernization in modern times was first infiltrated through calendrical science.

Western astronomy had arrived in China with the Jesuits in the sixteenth century. Calendar-making was a vital function of the Chinese bureaucracy, and the Jesuits hoped that by demonstrating the superiority of Western astronomy they would succeed in persuading the bureaucratic elite that Western cultures and Christianity were superior. Astronomy was well suited to their purposes, not only because it was so important to the Chinese bureaucracy but because the phenomena with which it dealt possessed a universality that transcended ► [East and West](#), and the objectivity of celestial phenomena did not permit much human manipulation. Furthermore, it was quantitatively precise. Thus, when the tally sheet was in, Chinese astronomers had to acknowledge that Western astronomy had superior features. All that the Jesuits made available from Western tradition, however, were peripheral data and methods of calculation. The structure, styles, and purposes of Chinese calendrical astronomy remained unchanged. As Xu Guangqi, a high Chinese official who collaborated with the Jesuit Matteo Ricci on several projects, put it, “We melted down their materials and poured them

into the *Datong* (the traditional Chinese calendar then in use) mold.”

In Japan, the eighth Shogun Yoshimune (1644–1751) attempted to use this refurbished Chinese astronomy as the basis for calendrical reform, but he was effectively opposed by conservative court circles in Kyoto. The revision of Horeki that came into effect in 1754 was still modeled upon the traditional *Shoushi* calendar. Yoshimune’s desire was fully realized, however, in the Kansei revision of 1797.

After that, the scientific quality of the traditional luni-solar calendar was improved and perfected, but still the traditional mold was maintained throughout the Tokugawa period (1603–1867).

Despite the earlier recognition of Western superiority in science, a radical change of political institutions in Japan had to precede the official adoption of the Western Gregorian calendar in 1873. The decisive factor in the adoption of the Gregorian calendar was the high value the government placed on westernization. Many Japanese proposed a more reasonable solar calendar at the time of the reform, but the government preferred the Gregorian, despite its obvious shortcomings, because of diplomatic relations with the West.

With the establishment of the Republic of China in 1912, the Chinese luni-solar calendar was officially abolished.

To what extent the Gregorian calendar was observed among the populace is questionable, but after the second World War, it became firmly established in everyday life in East Asia.

Calendars in Egypt

Jehane Ragai and Gregg De Young
The American University in Cairo, Cairo, Egypt

Otto Neugebauer (1969, 81) described the ancient Egyptian civil calendar as “the only intelligent calendar which ever existed in human history.” His statement can be appreciated by tracing the ancient Egyptians’ gradually developing sense of time from an initial awareness of the day to the full realization that the year had a constant length of 365 days. The introduction of the Egyptian civil calendar, based on solar years as opposed to lunar years, resulted in the development of our present-day Gregorian calendar.

Humans first became conscious of the existence of the day through the regular reappearance of the sun after its disappearance the evening before. Observing the regular change of one crescent moon to the next, they became aware of the longer time unit of the month. The practical demands of temple administration led them to develop their ability to count and calculate and they realized that one lunar month was made up of 29 or 30 days.

With the advent of agriculture in the Nile Valley, the season, rather than the month, gained importance as a subunit of the year. This agricultural calendar was based on a regularly recurring event, the Nile flood, whose return it was desirable to predict with a fair degree of accuracy. The ancient Egyptians must have realized that a purely lunar calendar was not capable of

adequately predicting such annual events. They hit upon another device by which the onset of the inundation could be determined – the heliacal rising of Sothis (Sirius, the brightest star in the sky). They observed that after a 70-day period of invisibility, Sothis could be seen again just before sunrise, and this heliacal appearance of the star was taken to signal the beginning of the new year.

The Egyptians, having reckoned that there was a 365-day span between two successive heliacal risings of Sothis, initially resorted to a luni-stellar calendar which consisted of 12 lunar months totaling 354 days, to which an additional intercalary month was added every few years to make up for the cumulative discrepancy arising from the 11-day difference between the lunar and stellar year. The rule used was that whenever Sothis rose during the last 11 days of the fourth month of the last season, an intercalary month should be added.

Although the luni-stellar calendar could set the time for observance of religious festivals, which were typically agricultural in origin, a more practical calendar was required to meet the demands of the state administrative system. Thus, the Egyptians adopted a 365-day civil calendar which was divided into three seasons, each of four 30-day months. The year consisted of 12 months, each of 30 days, plus “five days upon the year.” Events were officially dated as occurring on the first, second, third . . . day of the first, second, third . . . month of the specific season of a particular year in the reign of the current pharaoh. In New Kingdom documents, the 12 months are often given individual names which originated from the cultic celebrations connected with these months: (1) Thoth, (2) Phasphi, (3) Altyr, (4) Choriak, (5) Tybi, (6) Mechir, (7) Phamenoth, (8) Pharmuthi, (9) Pachon, (10) Payni, (11) Epiphi, and (12) Mesori. These names of months are still preserved in Egyptian folk astronomy and meteorology.

Each of the 30-day months of the civil calendar was divided into three 10-day “weeks” or decans. Thus, there were 36 decans each year [Symons 2007]. The Egyptians defined each decan to begin when a particular star or

constellation appeared on the horizon just before sunrise. In the New Kingdom, the decan hours came to be measured in terms of the local meridian, rather than the horizon (Belmonte 2003). The period of time between the appearance of one decan on the horizon and the next was defined to be an hour. From the surviving “diagonal calendar” examples, it is clear that the night was considered to contain only 12 h rather than the 18 which might have been expected when we consider that we see approximately half the celestial sphere on any given night. The discrepancy seems to arise because the Egyptians did not include the period of twilight or dawn as part of the night. Only the period of totally darkened sky corresponded to the term “night.”

The idea that the day also included 12 h seems to be developed merely in analogy with the night. These hours might be measured on a shadow clock, since the length of shadow cast by any object changes relative to the position of the sun in the heavens. The shadow does not just change over the course of the day, however, but also over the course of the year as the sun travels between the tropics. As a result, these shadow clocks give no more than an approximation of true equal hours. The use of clepsydra (water clocks), in which water escapes from a graduated container at a regular rate, would provide a measurement closer to our modern concept of equal hours.

The Egyptian calendar constructors and time-keepers did not go beyond the hour in measuring time. It is to the Babylonians, with their sexagesimal mathematical system, that we owe our modern concepts of 60 min in an hour and 60 s in a minute.

In time, the Egyptian 365-day calendar became completely out of step with the actual tropical year, since it fell behind the latter by 1 day every 4 years. Thus, in 4×365 years, i.e., in 1,460 years, the civil year would have lost a complete solar year and would again correspond with the seasons. This 1,460-year period is generally referred to as the “Sothic cycle” and reflects the fact that every 1,460 years the so-called heliacal rising of Sothis fell on New Year’s Day and thus marked the onset of a new Sothic period. The Egyptians seem not to have

been concerned by the discrepancy between their civil calendar and the true solar year.

Early attempts to calculate the date of the introduction of the civil calendar based on the period of the Sothic cycle and on the assumption that the civil calendar would have coincided with the luni-stellar cultic calendar when it was first introduced have been discredited by more modern scholarship. At present, there is no satisfactory answer to the question.

In 238 BCE, Ptolemy III proposed to bring the civil calendar into synchronization with the solar year by adding an extra epagomenal day every 4 years. His attempt did not find widespread acceptance. Modification of the ancient calendar only ensued two centuries later when, after Julius Caesar’s conquest of Egypt in 46 BCE, he followed the advice of the famous Alexandrian astronomer, Sosigenes, and adopted a modification of the ancient civil calendar for the Roman Republic. Sosigenes suggested that the length of the year should be 365 and a quarter days, that there should be a 4-year cycle containing 3 years of 365 days and the fourth year containing 366 days, and that the year should begin on the first of January.

- Winlock, H. (1940). Origin of the ancient Egyptian calendar. *Proceedings of the American Philosophical Society*, 83, 447–464.

This calendar is based on the following imperfect parameters:

- Five sidereal years = 1,830 days
- Sixty two lunations = 1,830 days
- Sixty seven sidereal lunar months = 1,830 days

The star *beta Delphini* indicates the winter solstice (which was indeed the case around 1500 BCE) which is apparently a fixed point. The lunar orbit is divided into 27 equal arcs from *beta Delphini* each equal to 13°20', called *nakṣatra*, the first arc named *Dhaniṣṭhā*. The arcs are named after a prominent star of the division. The theory is that if, in 5 years, two lunations are intercalated, then the lunar year will remain tied with the solar one. This period is called a 5-yearly cycle or *yuga*.

In practice, a cycle begins when the sun and the moon are in conjunction at *beta Delphini* (i.e., from the winter solstice). The first, second and fourth year each contain 12 new moon ending lunations. One lunation is intercalated at the middle of the third year and another at the end of the fifth. The second cycle then again begins from a similar new moon at winter, solstice.

This imperfect calendar was destined to collapse, as the succeeding cycles will begin from new moons shifted by some 4.5 days from the winter solstice at *beta Delphini* per cycle, accumulating to one lunation in six or seven cycles. However, the calendar did not collapse, and so the accumulated lunation was extracalated, but we are not told in the text how this was done. Perhaps the rule is hidden in an obscure part of the text, and so we have to guess it.

A lunation is divided into 30 parts called *tithis*. Accordingly, 30 *tithis* = 1,830/62 days. The excess 30/62 of a *tithi* over a day is called an omitted *tithi*. A month's days are designated by the *tithi* of the day and not by ordinal numbers. The Jainas used this cycle in their calendar with a marginal change: that months were full-moon-ending and a cycle began from a full moon at summer solstice in the middle of the *Āśleṣā* division (180° away from *beta Delphini*).

Calendars in India

A. K. Chakravarty

Calendrical science developed in India in three distinct phases, and each phase influenced the succeeding one. The first phase produced the Vedic calendar, covering a period from an unknown antiquity to the Mauryan emperor Aśoka (ca. 300 BCE); the second had the Greco-Indian calendar for a short period between the post-Aśokan and post-Kuṣāṇa period (ca. AD 300). And the third produced the Siddhāntic calendar from the Gupta period (AD 319) which is still used in India today. All three phases are characterized by formulations of fitting a lunar year into a sidereal solar one by suitably intercalating lunations.

References to calendrical elements like lunation, intercalation, year, and solstice occur even in the earliest part of Vedic literature. A separate calendrical literature, deemed a part of the Vedas, was developed in a small text, *Vedāṅga Jyotiṣa*, but this text has not been fully deciphered yet. There are some astronomical statements in the text, and also in the earliest part of Vedic literature, which do not hold true in the latitude belt and in the time period when the Vedic Aryans are believed to have settled in India.

It is a separate course of study as to how and when the Vedic Indians obtained this calendar, but they adopted it without verifying it.

Kautilya wrote a book entitled *Arthaśāstra* which is believed to reflect the social and administrative conventions of the Mauryan empire. This book, on the subject of measuring time, only reproduced the Jain school of the 5-yearly cycle. We are thus assured of its use until then.

The second phase of the Indian calendar began by the first century BCE after Śaka penetration into northwestern India.

The Śakas, a central Asian people, conquered Bactria in 123 BCE and established an era with epoch at 123 BCE, now called the Old Śaka Era. This epoch has variously been fixed at 88 BCE (Konow) and 110 BCE (Herzfeld), but, as M.N. Saha has shown, 123 BCE fits into all the circumstantial evidence.

The Śakas used the Greek calendar based on the Metonic cycle in their homeland. This was a 19 year cycle at whose beginning and end the sun and moon are in the same relative position to each other. When they reached India they adopted Indian culture and Aryanized or Indianized the Greek calendar, producing a Greco-Indian calendar. It replaced the classical 5-yearly cycle and it circulated in India up to ca. AD 200. The Kuṣāṇas, another Śaka tribe, penetrated further inside India, adopting Indian culture and using this calendar. Kings of the Śaka and Kuṣāṇa dynasties left behind some inscriptions bearing dates. These always refer to an era, as in era of king Kaṇiṣka. Further, they contain a mysterious expression – *etaye purvam* – whose meaning has not been deciphered.

The Indian form of the calendar is that the months are full moon ending; the 19-year cycle begins from a full moon at the autumnal equinox in the month Kārtika; months are assigned Sanskrit or Sanskritized Greek names; and, in special cases, the day is designated by the moon’s *nakṣatra* on that day. The Greek form is that days are designated by ordinal numbers and not by *tithis*, and intercalation is made at the middle of the year in Chaitra.

All these features are fully reflected in the inscriptions of the Kuṣāṇa kings. For example, present researches have shown that Kaṇiṣka established his era in AD 78 after deleting the 100th place in the old Śaka era for that year.

Now, $123 + 78 = 201 = 1$, deleting the hundredth place. Hence, AD 78 = 1 Kaṇiṣka era (current) and 0 Kaṇiṣka era (elapsed).

We interpret *etaye purvam* as elapsed year, and accordingly the Julian equivalent of Kaṇiṣka era in these inscriptions is:

$$AD 78 = 0 \text{ Kaṇiṣka era.}$$

The day of the month can also be identified with the *tithi* with tolerable accuracy. We have seen that the moon gains 12° over the sun per *tithi*. In case of new-moon-ending months, we should expect, on 20th Āṣāḍha:

- Moon – sun = $20 \times 12^\circ = 240^\circ$ (near about)
- Or sun = moon – 240° .

If the moon is near *Uttara Phalguni* (tropical longitude in AD 90 = $144^\circ 46'$), we should have: sun = $144^\circ 46' - 240^\circ = 265^\circ$ (say), so that the sun’s position comes near the winter solstice, which cannot happen in Āṣāḍha. However, if the month is full-moon-ending, then the moon-sun = $5 \times 12^\circ = 60^\circ$, or sun = moon – $60^\circ = 144^\circ 46' - 60^\circ = 85^\circ$ (say), i.e., near the summer solstice, which indeed happens in Āṣāḍha.

If we compute the mean tropical longitude of the sun (L) and mean elongation of the moon in days (D), we get (Table 1):

These lunisolar positions are in complete agreement with the inscriptional dates. We may perhaps identify these dates as Julian equivalents of the inscriptional dates. Using this scale we can decipher all the other dates in the inscriptions of the Kuṣāṇa kings and use the same method to decipher the dates of the old Śaka Era.

This second phase was short-lived, but had far-reaching effects on the later Indian calendar. In fact, this was perhaps the most productive period in Indian calendrical history.

Calendars in India, Table 1 In a period of 4,320,000 years

Date	L	D
June 21, AD 90	$87^\circ.16$	4.81

This Greco-Indian calendar was discontinued after the fall of the Kuṣāṇa empire.

In the third phase, the Indian calendar was thoroughly revised. New calendrical elements were introduced, new techniques in computational works were formulated, and the application of cycles for intercalation was abandoned. The new calendar that emerged is called the Siddhāntic calendar. This calendar was perfected by later Indian astronomers and is still used all over India with some marginal changes in some regions. In this phase the solar zodiac with 12 signs was introduced. The *nakṣatra* division was recast so that the first arc-division, renamed *Aśvinī*, began from the first sign *Meṣa* (Aries). This common point was the vernal equinox. By AD 550, the vernal equinox shifted to *zeta Piscium*, and this star (or a point very close to it) has since been the beginning of the Indian zodiac.

The new technique for computations was that an epoch, *Kaliyuga*, was formulated such that all the luminaries, like the sun, moon, and planets, were assumed to be in conjunction at the initial point of the zodiac at this epoch. Sidereal motions of the luminaries were so assigned that each of them made an integral number of revolutions in a period of 4,320,000 years (see Table 2).

Astronomical parameters in this phase were not uniform in different schools. We cite below some calendrical parameters from the Āryabhaṭian school (AD 476) and the *Sūryasiddhānta* school of the tenth century.

For any day in question, elapsed days from Kali are computed from the above figures, and from the rates of sidereal motion of the luminaries their positions are found in the zodiac. The epoch of *Kali* was computed by Bentley at 18th February, 3102 BCE midnight at Ujjain (longitude 75°45' east). This date has been generally accepted by all astronomers.

► **Āryabhaṭa** formulated corrections of mean motions of the luminaries, but such formulations are not found in earlier works. Our presumption is that only mean motions were considered in the pre-Āryabhaṭian period.

In this revised calendar, the luni-solar year begins from the new moon just preceding the

Calendars in India, Table 2 In a period of 4,320,000 years

	Āryabhaṭa	<i>Sūryasiddhānta</i>
Sidereal revolution of the sun	4,320,000	4,320,000
Sidereal revolution of the moon	57,753,336	57,753,336
Sidereal revolution of Jupiter	364,224	364,220
Total civil days	1,577,917,500	1,577,917,828
Intercalary lunations	1,593,336	1,593,336
Omitted <i>tithis</i>	25,082,580	25,082,252

sun's entry to the initial point in the spring month *Chaitra*. Now, 12 lunations fall short of 10.8 days from a sidereal year, and this accumulates to one lunation in 2 or 3 years. Whenever such an extra lunation forms, it is intercalated in the year; there is no role of any cycle here. This luni-solar year, with days designated by the *tithi* of the day, is used all over India for religious purposes.

A solar year is also devised beginning from the sun's entry into the first sign *Meṣa*, and is divided into 12 solar months, each month being the period the sun stays in a sign. Days of solar months are designated by ordinal numbers. The first month is *Vaiśākha*. Datings are recorded by luni-solar year in some regions, and by solar year elsewhere. The era generally used is the Kaṇiṣka era renamed the Śaka era.

In a year containing 12 lunations, the 12 new moons will, most generally, be distributed over the 12 signs, i.e., each sign will contain a new moon. However, in an intercalary year when 13 lunations are distributed over 12 signs, 2 new moons must occur in 1 sign, and in extreme cases, 1 sign may not contain any new moon at all. Such situations are natural phenomena and are no problem for astronomers.

Out of the 13 lunations occurring in an intercalated year, any one may be earmarked as the extra month. However, metaphysics has taken a toll here. As one sign will contain two new moons, so two lunations, one from each new moon, will occur in that sign. One lunation out of these two has to be selected as the intercalary

one. Volumes of religious literature have been written, perhaps more voluminous than their astronomical counterparts, on which lunation is the proper one and which is the intercalary one. Similarly, when a sign becomes void of a new moon, religious literature is controversial as to which lunation is to be assigned to that sign. Almost every region of India has its own convention on these points.

Calendars in Islam

Mohammad Ilyas

Even the most ancient peoples considered the day the earliest unit of time-telling. However, the day is not convenient for long intervals of time. Even allowing for a primitive lifespan of 36 years, a person would live some 13,500 days, and it is very easy to lose track of some of those.

It seems natural to turn to the Earth's next most prominent body, the moon, for another unit. Here, the readymade period of the lunar phases provides the natural unit called the *lunar month*. The lunar month is approximately 29.5 days (more exactly 29.5306 or 29:12:2.8). In pre-agricultural times, the month provided a convenient and simple method for measuring moderately long periods of time. A lifetime of something like 400 months is a more convenient figure than 13,500 days. Lunar months united to the seasons, as they would have been initially, would produce some problems for a settled agricultural society, which is not the case for a hunting or herding society of nomads, who could wander more freely in search of grain or grass. Farmers not only had to stay where they were, but also needed to increase their chances of a good harvest by sowing at a proper time to take advantage of seasonal rains and seasonal warmth. Therefore, to keep the lunar months approximately seasonal, an intercalary month needed to be added in 7 of each 19-year cycle (19 solar years = 235 lunar months, i.e. 19 lunar years of 12 months each, +7 lunar months). In due course, the practice of intercalation was gradually perfected; the intercalary months came to be added in the 3rd, 6th, 8th, 11th, 14th, 17th, and 19th year of each cycle, in a popular scheme which transformed the lunar calendar into a seasonal, or lunisolar calendar, in which a month remained in pace with the sun to within 20 days.

The lunisolar calendar practice was adopted by the Hebrews, Greeks, and Romans and remains in use in the Jewish, Hindu, and Chinese calendars of today. The early Christians continued to use the Jewish (lunisolar) calendar tied to the new moon for more than three centuries and established the day of Easter on that basis. On the other hand, the Roman Republic, which had also used a lunisolar calendar for a long period, moved to a purely solar calendar in 46 BCE as a result of abuse of power by Pontiffs in the matter of intercalation.

Julius Caesar decided to put an end to this chaotic situation by introducing the solar calendar system. In this transformation, 46 BCE was allowed to continue for 445 days (!) and came to be known as “The Year of Confusion”, in effect the last one. The adopted solar calendar with a year length of 365.25 days became known as the Julian calendar.

The month, being tied to the moon, begins at a fixed phase in the lunar calendrical system. Since any phase will do, the month can begin at each full moon, the first quarter, etc. However, the obvious way is to begin each month with the new moon – on the evening when the growing crescent first becomes visible immediately after sunset. Practically all lunar calendars began their new months with the new visible crescent. Some modern users of the lunar calendar (the Chinese and Jews) have changed this to the astronomical new moon, i.e. the conjunction, while Muslims maintain the first visible phase of the new crescent as the beginning of a new month.

The Islamic calendar was both a religious as well as a civil calendar, necessary to determine periods of the annual month-long fast, pilgrimages, times of marriage and divorce, years of taxes on wealth for the needy, religious observances, and general and historical timekeeping.

In Arabia, the use of a lunar calendar is known to have existed from very early times. The original practice is believed to have been to use 12 lunar months to a year. On the pre-Islamic Arab calendar, the annual Pilgrimage (*Hajj*) to *Ka'bah* in Mecca was a most significant and

important event. Although the event of the pilgrimage to *Ka'bah* was basically religious, it was also important for trade and business. When the *Hajj* was out of season, it created difficulties in procuring the crops and sacrificial animals for trade and use. To overcome this, the Arabs in Mecca are believed to have introduced a system of intercalation known as *al-Naasi*. A Meccan by the name of Qalmas is reported to be the first person assigned this task who, during each pilgrimage, would announce the dates for the coming years' *Hajj* and inform whether the intercalation was due for the coming *Hajj* season.

In addition to the month of *Dhu'l-Hijjah* (in which the pilgrimage is held), three other months (*Rajab*, *Shawwal*, and *Thu'l Qa'dah*) were sacred to the pre-Islamic Arabs. During these months, certain things, such as wars with opponents, were forbidden. In time, the practice of intercalation was much abused (as with the Roman calendar) thus affecting the sacred months and the related prohibitions by changing a sacred month into a non-sacred one.

The calendar in use in Medina (North of Mecca) remained in the original “twelve months to a year” form. The early Muslims continued to use the Meccan calendar while in Mecca, but shifted to the *Medinan* calendar after the Prophet Muḥammad and his companions migrated to Medina in AD 622. Following the conquest of Mecca in the eighth year of *Hijrah* (December AD 629), the Muslims continued to use the *Medinan* calendar, and the *Meccan* calendar ran parallel.

However, during the Prophet Muḥammad's last pilgrimage in the tenth year of *Hijrah* (AD 632), the Meccan practice of intercalation was abolished through a Quranic injunction, thus reverting the Arab-Islamic calendar to the simple “twelve months to a year” practice.

The Islamic calendar also required that the beginning of a month be based on the first sighting. This was particularly important for religious events like the beginning and end of the fasting month and the date of the pilgrimage to the *Ka'bah*.

There was no commonly accepted permanent calendar in pre-Islamic Arabia. Nevertheless, the custom of counting years was, in one form or another, prevalent among the Arabs and their neighbours. Opinions are divided as to the origin of this practice. According to Ibn al-Jazwī, it dates from the time when the children of the prophet Adam multiplied and spread on earth. In South Arabia, a calendar system originated in 115 or 109 BCE when the Himyarites adopted one using the reigns of the Tubba as the epoch years of their era. The inhabitants of Sanaa (Yemen) also adopted a calendar, using the victory over the Yemen by the Abyssinians, and later, the Persian conquest.

The origin of a chronology of events in North Arabia may be traced as far back as the construction of the *Ka'bah* by the prophet Abraham and his son the prophet Ismail. The northern Arabians are also reported to have their famous battle days as marking epochs of eras. A local calendar is supposed to have existed in Medina also. Al-Masudi maintains that the people of Medina used the dates of their castles and palaces as their local calendar at the time of the prophet Muḥammad's migration, but others reject this, claiming the adoption of an era by the people of Medina to a month or two after the prophet's arrival, which continued until his death in AD 632. According to a widely held view, the *Hijrah* era was set up at the time of Caliph 'Umar ibn al-Khattab in AD 637/638, i.e. about 5 or 6 years after the introduction of the purely lunar calendar. After many consultations, the year of the prophet Muḥammad's *Hijrah* was accepted for the beginning of the Islamic (or *Hijrah*) calendar.

Based on scientific understanding, certain ground rules were laid down which form the part of *sharī'ah* (the Islamic legal system) governing the calendar. Some of these were:

1. The length of a month should be 29 or 30 days.
2. The length of a year should be 354 or 355 days.
3. The maximum number of consecutive 30-day months is 4; the maximum number of consecutive 29-day months is 3.

4. Each new month begins with the first light of the new crescent moon visible on the western horizon after sunset.
5. One should try sighting the new moon on the 29th day of the month, but if it cannot be seen (even due to clouds), complete the month as of 30 days.
6. The visual sighting report must be corroborated by a witness.
7. The persons involved in the reporting must be reliable, adult, truthful, and sane, with good eyesight (implied). They are punished if proved to be purposely misleading.
8. The visual sighting report should not conflict with basic scientific understanding and natural laws. Indeed, professional scientists' involvement is essential to ascertain the reliability of the reported sighting, and the scientific test would include a check on related parameters (e.g. the shape of the crescent, its position and altitude, time of observation, sky conditions).
9. The sighting must be carried out in an organized way every month.

Sharī'ah also allows for the correction of a mistake. If on the 28th day of an Islamic month, the new moon has been sighted, a correction will be made to the beginning of the month, since a month should have only 29 or 30 days. If the month concerned is *Ramaḍan* then an extra fast would have to be completed after Eid celebrations.

Clearly, earliest visibility of the new moon plays a very critical role in Islamic calendar regulation. The Islamic "State" placed special emphasis on astronomy research, and it became a standard element in formal religious and legal education. The early Muslim community, based under the clear skies of Arabia and assisted by State-sponsored research, had no serious problems in following these injunctions to regulate their calendar. Muslims contributed enormously to the development of the science of the new Moon's earliest visibility and its advance prediction for greatly varying geo-environmental situations. In this, they built upon the work of earlier researchers as well (e.g. Babylonians, Hindus,

Jews). Besides the rigorous science, simple schemes were devised to construct long-term calendars especially to interconvert Islamic dates with Christian and other lunisolar calendrical dates. Based on technical information, one of the simple schemes (known as the schematic or *Istalahi* system) involved a cycle of 30 lunar years in which months approximately alternate between 29 and 30 days and 11 years consist of 355 days, the rest 354.

Backed by extensive research, Muslim scientists developed visibility tables and produced many reference works. All were well when astronomy and scientific endeavour were at their zenith in the Muslim lands.

Scientific interest in predicting the time of the first (earliest) new Moon sighting (for a clear sky) goes back to a period at least as early as the Babylonian era. Based on careful observational data, a simple criterion was developed and passed on to the Muslims through the Hindus, apparently with very little further improvement. This problem was thoroughly investigated by the early Muslim astronomers in the eight to tenth centuries AD and included such notable persons as ► [Ḥabash al-Ḥāsib](#) and ► [al-Battānī](#). The physics-based system(s), developed up to the eleventh century, saw very little further development until more recent times, when improvements were made. There has also been a series of simpler criteria involving time difference (lag) between moonset and sunset and the “age” of the moon.

Calendars in Mesoamerica

Tom Jones

For many reasonably educated persons, the greatest single achievement of ancient Mesoamerica was the Maya calendar. In fact, a calendar was in use throughout Middle America, but it is its Maya form that has captured the world's imagination, the claim often being made that its accuracy exceeded that of the calendar in use in Europe at the time of the Conquest and, by some, even of that which we use today. While most of their neighbors kept account of time with three periods of differing numbers of days, the combinations of which formed a repeating calendar of 18,980 days, the Maya employed a mechanism that synchronized these same periods and others of their own making with a system that tracked cumulative time.

This cumulative record, or ► [Long Count](#), expressed historical dates with five-place numbers that recorded days accumulated from an arbitrary zero-point which has been determined to correspond to August 13, 3114 BCE in our present Gregorian calendar. (The correlation of Maya dates to European are to the no-zero-year Gregorian calendar, employing Thompson's 1935 correlation of 584,285 days.) Accumulating 1-day (*k'in*), 20-day (*winal*), and 360-day (*tun*)

Calendars in Mesoamerica, Fig. 1 The names and values of the Long Count places with their respective glyphs (Drawings by the author)

PLACE	NAME	DAYS	CALC	VALUE	GLYPHS
1	<i>K'in</i>	1 day	(1 X 1)	1 <i>K'in</i>	
2	<i>Winal</i>	20 days	(20 X 1)	20 <i>K'inob</i>	
3	<i>Tun</i>	360 days	(18 X 20)	18 <i>Winalob</i>	
4	<i>K'atun</i>	7200 days	(20 X 360)	20 <i>K'atunob</i>	
5	<i>Bak'tun</i>	144,000 days	(20 X 7200)	20 <i>Bak'tunob</i>	

periods, the Long Count employed a qualified vigesimal (20-base) place-number system – the qualification being an 18-base for the third place. The names and values of the Long Count places, from the unit up, were expressed in the writing system with distinct hieroglyphs for each order of magnitude (Fig. 1).

Thus, for example, a Long Count date with the numerical value of 9 *bak'tunob*, 8 *k'atunob*, 9 *tunob*, 13 *winalob*, and 0 *k'inob* records a day that was 1,357,100 days after August 13, 3114 BCE, which is to say March 26, 603. These values were communicated by positioning the numbers as prefixes or superfixes of the glyphs for the periods. The *-ob* inflection of Mayan nouns indicates plural. Because double digits are often required to express decimal equivalents of numbers in the places of the Maya system, Mayanists have adopted the convention of inserting periods between the places of Long Count dates. The above date, for example, is written 9.8.9.13.0. Though Maya historical dates that employed the Long Count were generally limited to five places, the calendrical system itself was open-ended and, when called upon to do so (as to meet mythological needs) could accommodate any number of places and express any full number of days. The greatest known to have survived is recorded at Coba as 13.13.13.13.13.13.13.13.13.13.0.0.0.0, which expressed in our decimal-system amounts to almost 22 quintillion tropical years!

Long Count dates were carved on monuments in the Maya heartland for over 600 years, the earliest known being 8.12.14.8.15 (8 July 292), the latest 10.4.0.0.0. (20 January 909). Moreover, the *Dresden Codex* records the much later date, 10.17.13.12.12 (29 October 1178). Though extensively used by the Maya, the Long Count was probably not their invention. Earlier Long Count dates have survived on several monuments on the southwestern Maya periphery – the earliest, 7.16.3.2.12 (7 December 36 BCE), at Chiapa de Corzo – in what was probably a proto-Zoquean (non-Mayan) speaking area.

The Maya coordinated this cumulative Long Count with the pan-Mesoamerican repeating calendar of 18,980 days. Known generally as the Calendar Round and called the *xiuhmolpilli* by the Aztecs and *hunab* by the Maya, this period consisted of three component cycles of 13, 20, and 365 days. The first two of these were a set of consecutive day-numbers (1–13) and a set of 20 day-names specific to each of some 60 language-groups within Mesoamerica (Fig. 2). The permutations of the 13 numbers and 20 names designated each passing day with a combination that repeated every 260 (13 × 20) days. This resulting 260-day period was termed the *tonalpohualli* by the Aztecs and is called the *tsolk'in* by Mayanists. Mesoamericans visualized this period as a four-sided cosmogram (Fig. 3) that can be described as a “Maltese” cross (the broad arms of which are identified in a counterclockwise order

as East, North, West, and South) superimposed over a “St. Andrew’s” cross (the narrow arms of which define the diagonal directions Northeast, Northwest, Southeast, and Southwest). The eight projecting arms of this scheme are each comprised of 13 days proceeding out from the center and 13 more returning, with the four outer edges of the “Maltese” arms also each contributing 13 to complete the round of 260 days. This 260-day *tonalpohualli* was the most significant aspect of the calendar for the daily life of the typical Mesoamerican. It formed the basis of numerous rituals, character evaluations, omens, and prognostications, traced out in Aztec, Mixtec, and Maya books.

While the 260-day ritual period seems to have been the result of the combination of a cultural fascination with the number 13 and a vigesimal counting system derived from the number of digits of the hands and feet, the 365-day period – the Maya *haab* or Aztec *xihuitl* – to which we now turn, was an attempt at a full-number approximation of the tropical year (of 365.2422 days, as calculated today). This “vague year” was achieved by a set of 18 named periods of 20 consecutively numbered days each, and five extra consecutively numbered terminal days (*Nemontemi* in Aztec, *Wayeb* in Maya) to total 365 days ($18 \times 20 + 5$) (Fig. 4). Every day, then, could be expressed with a day-number, a day-name and a numbered position in one of the periods of the “vague year.” The workings of this

Calendar Round system are well illustrated by comparing the modes of expressing succeeding dates that include the five terminal days of the vague year in the Aztec *xiuhmolpilli* and Maya *hunab* (Fig. 5). The presence of these 5 days causes the position of any given *tsolk'in* day to drop back by 5 days with each successive vague year. Because 260 and 365 share a common denominator of 5, any specific combination of day-number, day-name, and vague year position repeats every 18,980 days ($260 \times 365 - 5 = 18,980$), or about 13 days short of 52 tropical years. As with the ► [Long Count](#), evidence for the origins of the Calendar Round lies beyond the western pale of the Maya, dating from as early as the sixth century BCE in the Zapotec region.

The *xiuhmolpilli* was of particular importance to the Aztecs, whose mythology claimed that the age in which they lived and in which the current Sun-God, *Tonatiuh*, reigned was preceded by four earlier ages, each with its own sun and each of which had been destroyed in its own way – the first by devouring jaguars, the second by winds, the third by a rain of fire and the fourth by a world-flood. During this fifth era, under *Tonatiuh*, the future seems to have been doled out to the Aztecs one *xiuhmolpilli* at a time. Each successive *xiuhmolpilli* had to be freshly solicited by a great deal of bloodletting and an elaborate “New Fire” ceremony that was carried out during the five *Nemontemi* days of each 52 *xihuitl*. If, following the ceremony, the stars continued on

their steady march across the midnight-sky of the last day of the *xiuhmolpilli* – presumably because the gods had found the ritual to their satisfaction – the people could be assured that another 52 “years” had been granted them.

In the Maya region, this endlessly repeating pan-Mesoamerican cycle was synchronized with the accumulated days of the Long Count as the mathematical consequence of the arbitrary assignment of the Calendar Round date 4 'Ahaw 8 *Kumk'u* to the Long Count zero-date (13 August 3114 BCE). Written out in full and preceded by a distinctive hieroglyph that served to introduce them, dates so synchronized stood at the very beginning of the hieroglyphic texts on the carved monuments of Mayadom – whence their designation, Initial Series dates. To take an example, the Initial Series date on Quirigua Stela I (Fig. 6) – which reads in typical Maya fashion, from top-left to bottom-right, two columns at a time – displays a large initial series introductory glyph (ISIG) in the initial position (A1–B2) followed by the Long Count 9.18.10.0.0 (A3–A4) and the Calendar Round 10'Ahaw

8 *Sak* (B4), establishing a date corresponding to August 19, 800. (Glyphs are conventionally located by assigning upper-case letters to the columns of a text, numbers to its rows, and lower-case letters to divisions within the glyph-blocks and designating them in that order, as A3, C2a, F7b, etc. Number-values are dots for 1, bars for 5, and various special symbols for 0).

At times, supplementary to the Long Count and Calendar Round and inserted parenthetically between the *tsolk'in* and *haab* entries, were glyphs that recorded additional cycles of 7 or 9 days duration, as well as certain lunar information. Supplementing the cycles mentioned, the Maya tracked one of 819 days – a product of three basic periods ($7 \times 9 \times 13$) – relating it to a 4-day cycle (which the Aztecs also recognized) that linked each day with one of the four cardinal directions and associated colors (East, red; North, white; West, black; South, white). On Piedras Negras Stela 1 (Fig. 7), for example, the ISIG (A1) is followed by the ► Long Count 9.12.2.0.16 (A2–A6) and the *tsolk'in* position 5 *Kib* (A7), while the *haab* position, 14 *Yaxk'in*,

Calendars in Mesoamerica, Fig. 6 Quirigua, Stela I: hieroglyphic text with Initial Series date (Drawing after Annie Hunter. From *Biologia Centrali-Americana*, by Alfred P. Maudslayi, reprinted in 1974 by Milpatron publishing corp. Used with permission of the publisher)

Calendars in Mesoamerica, Fig. 7 Piedras Negras, Stela 1: hieroglyphic text (Drawing by John Montgomery)

does not appear until eight glyph-blocks later (C2). The intervening blocks include two that record the seventh position of the 9-day cycle (A8–A9), one that records the moon’s age as 8 days (A10), another the moon’s number as third in a set of six (A11), two that name the moon (B1–C1), and one that identifies it as a 31 month (B2). Following *14 Yaxk’in* are four noncalendrical glyphs (B3–E1) describing the event of the Initial Series date (July 7, 674).

When there was a need to record multiple dates, each new one (expressed as a Calendar Round date) was typically linked to its predecessor by what scholars call a Distance Number. The Distance Number employed the same place system as the Long Count, but because the number of days to be recorded usually did not require all five places, they were entered in the reverse order of the Long Count – commencing with *k’inob*

and proceeding only through those higher places necessary to record the distance. Thus on the Piedras Negras stela, following the initial event, come two glyphs that record the Distance Number *15 k’inob*, *9 winalob*, and *12 tunob* (D2–E2), then two more that indicate an advance of that distance forward in time (D3–E3), and finally, two glyphs that record the Calendar Round date, *9 Chuwen 9 K’ank’in*. The calendrical mathematics are:

9.12. 2. 0. 16	5 <i>Kib</i>	14 <i>Yaxk’in</i>	(July 7, 674)
+12. 9. 15			
9. 12. 14. 10. 11	9 <i>Chuwen</i>	9 <i>K’ank’in</i>	(November 16, 686)

After two noncalendrical glyphs (F2–G2) that describe the event of the date so reached, come a second Distance Number, *5 k’inob* (F3), and the resulting third Calendar Round date,

1 Kib 14 K'ank'in (G3–G4). The mathematics are:

9.12. 14. 10. 11	9 Chuwen	9 K'ank'in	(November 16, 686)
+5			
9. 12. 14. 10. 16	1 Kib	14 K'ank'in	(November 21, 686)

This new date is followed by the single glyph that describes the event (G5). Then come the Distance Number, 5 k'inob, 2 winalob, and 1 k'atun (G6–G7), a fourth Calendar Round date, 5 Imix 19 Sak (G8–G9), and fourth event (G10–G12). This final calculation is:

9. 12. 14. 10. 16	Z1 Kib	14 K'ank'in	(November 21, 686)
+1. 0. 2. 5			
9. 13. 14. 13. 1	1 Imix	19 Sak	(September 23, 706)

As was the case for the second of these two monuments, the Maya often accompanied their calendrical entries with lunar data. From this propensity and from the structure of a Lunar Table in the *Dresden Codex*, it is clear that their concern was to anticipate eclipse-possible dates. Because eclipses (both lunar and solar) can only take place during a period of 18 days on either side of node-passage of the Moon over the path of the Sun, which occurs twice during a tropical year, the Maya grouped the months in semesters of six (and for corrective purposes, occasionally of five). In an attempt to approximate the Moon's 29.53059-day synodic period (as calculated today), they ascribed 29 and 30 days, alternately, to successive months, compensating for the gradual accumulation of excess time by introducing an extra 30-day month at predetermined intervals. One result was the *Dresden Codex* Lunar Table with its eclipse-period of 11,960 days, or just over 405 complete lunations. However, that excess time would be allowed to accumulate until after eight repetitions of the period (95,680 days), when the table could be adjusted to correspond more closely to the moon's position by subtracting 1 day. The mathematics behind this adjustment are: $29.53059 \times 405 = 11,959.88895$; $11,960 - 11,959.88895 = 0.11105$; $11,960 \times 8 = 95,680$; $11,959.88895 \times 8 = 95,679.116$;

$95,680 - 95,679.116 = 0.884$, or 21.216 h. To further refine the Lunar Table's use, follow-up adjustments had to be made with succeeding repetitions of the cycle.

Though not central to the calendar itself, the planet Venus was nevertheless also a concern of Maya calendrical savants. Observations and calculations recorded in the inscribed monuments show that the Maya employed a 584-day period to predict culturally important points in the planet's synodic period. Both the Maya and the Aztecs assigned numerological significance to the correspondence between five of these Venus-periods and eight *haabs* ($5 \times 584 = 2,920$; $8 \times 365 = 2,920$). Also, in the *Dresden Codex* is an elaborate table that consists of 13 sets of five periods of 584 days, or 37,960 days. Here again, because of the discrepancy between the full number 584 and the actual synodic period of Venus (583.97 days, by modern measurements) and because of the added cultural requirement that the first heliacal rising of the planet should occur on the *tsolk'in* date 1'Ahaw, an adjustment like that in the Lunar Table had to be made after several runs of the Venus Table.

The Mesoamerican calendar, if by no means invented by the Maya, nevertheless reached its most elaborate form at their hands. Tracking basic periods of 4, 7, 9, 13, 20, 365, and 584 days and greater periods that were the products of various combinations or lowest common multiples thereof – $260(13 \times 20)$, $819(7 \times 9 \times 13)$, $2,920(8 \times 365; 5 \times 584)$, $3,276(4 \times 7 \times 9 \times 13)$, $18,980(13 \times 20 \times 365)$ and $37,960(13 \times 20 \times 365 \times 2 = 13 \times 5 \times 584)$ days – and groupings of months of alternately 29 and 30 days in duration, they synchronized them all with the cumulative and open-ended [► Long Count](#) that recorded every passing day from its original 4'Ahaw 8 Kumk'u zero-point. Where the European calendar intercalated extra days as a device for keeping its dates in close harmony with the seasons (the vernal equinox, for example, occurring always on or about March 22), the Mesoamerican calendar, even in its most refined (Maya) mechanism, simply ground out the 1-day intervals of its several parts, accumulating or repeating them endlessly and without

interruption, all of its components creeping gradually backwards through the seasons. It was thus impossible to identify a position in the tropical year by knowing a Calendar Round date. The first 4 'Ahaw 8 Kumk'u fell on August 13, but the second fell 12 days earlier on August 1 and the third, 12 more on July 19. In the year 265, near the beginning of the Classic Period, after having returned to its original August 13 date 113 times, 4 'Ahaw 8 Kumk'u fell on May 16, and by the close of the Classic in the late ninth century, it had fallen back to December 15.

However skillfully the Maya may have combined their astronomical observations with calendrical calculations to predict lunar and solar eclipse stations, heliacal risings and settings, conjunctions, stationary points, and retrograde motions of the five visible planets, the fact remains that, for all its reputation, the calendar itself was no more accurate than the 365-day calendar the ancient Egyptians adopted around 4250 BCE which was the product of 12 30-day months ($12 \times 30 = 360$), plus – like the Mesoamerican *xihuitl* or *haab* – 5 extra days. Indeed, it was an Egyptian mathematician, Sosigenes, who, recognizing the faults of the rigid 365-day year, persuaded Julius Caesar to adopt his scheme for reforming the Roman calendar in 45 BCE, by intercalating an extra day every fourth year into an otherwise 365-day year. However, it would be unhistorical to judge the Maya calendar by a standard set by the Egyptian, the Julian, or the later Gregorian calendar. The cultural need of the Egyptians was to anticipate (for agricultural reasons) the annual flooding of the Nile. That of the Julian reform was to ensure that the Roman solstitial festival *foris fortuna* would fall regularly on June 22. The Christians, in turn, adopted the Julian calendar in 325 at the Council of Nicaea from a need to establish predictable dates for Easter, which – for religious reasons – had to fall on the first Sunday following the first full moon after the vernal equinox. It was this same need that led Pope Gregory XIII to authorize a further reform of the Julian calendar in 1582.

However, the cultural needs met by the Mesoamerican calendar were of a numerological-astrological nature. Quite apart from the

divinations of the purely numerical *tsolk'in*, the Maya assigned significance to astronomical predictions based upon complex multiples of their several whole-number cycles which were often linked to the actions of remote or fabled ancestors or mythological supernaturals or to multiples of the never whole-numbered synodic periods of the heavenly bodies. Contrived calendrical calculations into the remote past and distant future were made to establish mythological beginnings, regenerations, and calamities to come. Day-to-day events, even to the timing of military attacks or battles among themselves or surrender to the Spanish, seem to have fallen under this numerical spell. However closely the *Dresden Venus Table* may appear to approach a modern astronomical ephemeris of Venus, its purpose was to return the latter's heliacal rising to *I'Ahaw*, the birth date of the mythological Venus-associated hero, *Hunahpu* – irrespective of any temporary losses in accuracy its mechanisms may have produced. If the calendrical efforts of Mesoamericans can be described as an attempt to bring about a marriage between their whole-number numerology and their perceived rhythms of the Sun, Moon, planets, and stars, it was one in which it was the latter who were to love, honor, and obey. However, if the test of a good marriage is its durability, then the Mesoamerican calendar – particularly in its Maya form – was not only mathematically sophisticated, conceptually elegant, and visually beautiful, but a highly successful one as well.

Calendars in South America

R. Tom Zuidema

At the time of the Spanish conquest around the year 1530, the Incas had integrated different cultures, all belonging to Andean civilization, into a large empire, stretching from southern Colombia through Ecuador, Peru, and Bolivia, into northern Chile and Argentina. Much can be learned from the art of the Incas and their predecessors, including architecture, stone sculpture, pottery, and textiles. However, we have no access to written records as defined by western culture; understanding intellectual aspects of this civilization is almost exclusively dependent on what informants from Cuzco, the Inca capital in southern Peru, told the Spanish chroniclers. These were most impressed by Inca statecraft, although they were never present when it was still practiced. Their interpretation of Inca religion was heavily influenced by Christian opinions. Religion to them included memories of the Inca past and of state and private rituals related to, for instance, the calendrical organization of agriculture and llama husbandry. As Inca history is discussed in the article on [► Knowledge Systems of the Incas](#), this one concentrates on the calendar as it functioned in Cuzco.

Most of our information on the Inca calendar and related astronomical practices derives from only a few chroniclers: Juan de Betanzos [1551] (In case of an old text, square brackets indicate

the date of writing or first publication), a soldier and the first chronicler to write on this subject in the context of a full account of Inca culture; an anonymous author [ca. 1565] with precise information on the integration of astronomical observations into the calendar; Cristóbal de Molina [1574], a priest with great knowledge of Inca rituals but excluding those for one-third of the year; and Bernabé Cobo [1653], a late Jesuit author who gave our most comprehensive description of Inca culture including the calendar for the whole year. His information probably derives from a now lost account by Juan Polo de Ondegardo [1559], whose own description of the calendar only survives in a much revised short version [1585] for use by Catholic priests. Later chroniclers and dictionaries mostly follow Polo's version and add little information toward a reconstruction of the original Inca calendar. This reconstruction provides very different results from the general picture that the chroniclers present us with.

All chroniclers conceive the Inca calendar as consisting of 12 months. Notwithstanding this agreement, there is much confusion about the nature of the months, their order, and their correspondence to Christian months. Some of this confusion may derive from much local variation among calendars in the empire, but most of the blame is due to Spanish misreporting on the Cuzco calendar itself. Betanzos, Polo, and Cobo describe a system of 12 “months” with a fixed position in the solar year. Molina speaks of “months” and “moons” and refers to rituals according to the phases of the moon for three times of the year, roughly corresponding to June, September, and January. Some modern scholars therefore argue that the whole calendar was lunar, but this was not the case (Ziólkowski and Sadowski, 1992). On each of the three occasions important lunar rituals were celebrated after an independent solar observation had been made for that time of the year. We have no information on lunar rituals in Cuzco for other times of the year; we can only conclude that the integration of solar and lunar rituals in Peru was done in a way different from Western (Christian, Jewish) presuppositions in this respect.

There are various difficulties in accepting the Inca organization of months according to the Polo version of 1585. For instance, two names are taken together for 1 month that in other versions refer to separate months; in other calendars a name may be used as an alternative for either one or a next month. In some versions, a month name is suppressed for no apparent reason at all; months were said to be of rather different lengths, either longer or shorter than 30 or 31 days. And the anonymous chronicler mentions for two double-months that the moon observed in 1 month (either the first or the second) would always reach the other, leaving us to conclude that the fixed double-month was shorter than two movable synodic (lunar) months $2 \times 29\frac{1}{2} = 59$ days. Comparing the various descriptions of the Inca year, it becomes clear that originally it contained 13 and not 12 months and that each version suppressed one or another month name to accommodate this calendar to the Spanish one. It may have been a goal of Catholic missionaries fighting against "pagan" rituals, but there was also Inca consent, realizing the advantages of combining Inca and Catholic celebrations, first openly and later secretly.

From indications by Molina and Cobo we can conclude that the Inca calendar placed 1 month around the June solstice (21 June), celebrating *Inti Raymi* (feast of the sun), and 2 months, *Capac Raymi* (royal feast) and *Capac Raymi Camay Quilla* (royal feast, feast of the moon) around the December solstice, which honored the fact that in the southern hemisphere the sun is strongest then. For practical reasons, *Inti Raymi* may have been celebrated not on the days of the June solstice but within its month during the full moon either before or after in a given year. People took advantage of the dry season's clear skies when the moon shone the whole night.

During *Capac Raymi*, considerations were different. While the June solstice marked the middle of a month, the December solstice, six and a half Inca months apart, marked the date separating the 2 months of *Capac Raymi*. Moreover, these months fell in the middle of the rainy season when normally no good observations of the sun and the moon could be made. The month

of *Capac Raymi Camay Quilla* was celebrated, first awaiting the new moon with some celebrations. The major celebrations came with the next full moon and took some 7 days. If the new moon arrived early after the solstice (December 21), all celebrations took some 22 (15 + 7) days; but if it was late, they could take up some 52 (30 + 15 + 7) days. Then the full moon celebrations would not occur in *Camay Quilla* but extend into the next month. Although after those days the moon would still be visible late at night, no more attention would be paid. However, the day after these 52 days (February 13) was important for another reason. Then the sun in Cuzco – this city being $13\frac{1}{2}^{\circ}$ south of the equator and within the tropics – passes the zenith point in the sky at noon. Although the chroniclers were only vaguely aware of the importance of this event, Polo indicates that then a new year began, with people preparing for the coming harvest. The sun also passes the zenith 53 days before the December solstice, and we can assume that a similar calendrical calculation was made for this period. The anonymous chronicler considered it as one in which the moon of 1 month would always reach the other. Its beginning was celebrated with a feast, the *Itu*, which only Inca nobility could attend, and the last 6 days before the December solstice were also important for celebration. These days could begin with a full moon if the new moon had arrived late in this 53 day-period.

Apparently, the Incas divided the time from the first to the second passage of the sun through the zenith (107 days) into 4 months, of which the central ones of *Capac Raymi* were most important. The average length of the 13 months was about 28 days and as the connection to the length of a synodic month (29 days) was lost, there is no reason that the months could not be of various lengths as reported by the chroniclers. Having established the framework of the Inca calendar, an outline can be given of its ritual organization serving various, often contrasting, social needs.

The calendar organized, first, a multitude of sacrifices (llamas, guinea-pigs, birds, sometimes children) and offerings (mostly cultivated plants). The months were organized according to four seasons of 3 months and an independent

month after the sun's second zenith passage. Sacrifices and offerings expressed the different seasonal concerns.

A quite different organization of the months attended more political interests in terms of tribute due by Inca and non-Inca subjects and of the large feasts of state presented by the king, queen, and high nobility. In this organization, months were brought together in groups of two and then of four. This organization cross cut the seasonal one but kept the same independent month. Our first chroniclers mention how tribute was brought to Cuzco every 4 months and how non-Inca nobles accompanying these deliveries stayed for the same time in town. Betanzos adds to this that services of labor and distribution of food, especially meat and cloth, followed the same schedule. At first, the colonial administration showed interest in adopting this schedule for its own needs, but after about 1570 it changed to the European custom of having tribute paid twice a year, around Christmas and St John (24 June), and chroniclers no longer paid attention to the earlier system.

I mentioned above the most important 4 month-period around the December solstice. In between the times of planting and harvest, this was a season when the fields needed less attention and when heavy rainfall made travel difficult. *Capac Raymi* and its preceding month were dedicated to the initiation rituals of noble boys, these being assisted by noble girls who had had their own rituals of first menstruation at other times of the year. In the lunar rituals of *Camay Quilla* and the following month, noble men and women pledged their allegiance to the king, and rains were ritually dismissed awaiting the ripening of the fruits. In the 4 months around planting, land was first prepared for cultivation, ploughed and planted, and then rituals followed to help the budding plants grow and attract rains. Again, the two central months were dedicated to state rituals. First, the king himself helped with the planting. Keen observations were made of sunset throughout the first month to have the various timings for planting and irrigation of different sorts of plants, at lower, warmer and higher, colder places well orchestrated. In the second

month, dedicated to the moon, the queen, and women in general, "evil" and "illnesses" were ritually driven out of town in support of peace among people and of the growth of plants. Finally, the 4 months of harvest included the early harvest, the general harvest around Cuzco, the reception of foreign lords with their presents and the tribute of their people, and storage. Again the most important ceremonies occurred in the central months when first harvest was ritually brought into town and then the Inca himself ploughed, opening a new agricultural year, and ate with all nobles and foreign lords in the plaza.

Good descriptions of Andean rituals were also made for the central provinces around Lima, the vice royal capital in colonial times, and some of these ceremonies can be compared with Incaic ones in Cuzco. But when those other records became available in the early seventeenth century, more than 80 years had already passed after the Spaniards had arrived in the Andes. Much research still has to be carried out making those comparisons fruitful for a reconstruction of pre-Hispanic calendars in general.

Calendars in Turkey

Safiye Kıranlar

Sakarya University, Sakarya, Turkey

As a term, the word *takvim* (calendar) derived from the word “community,” meaning to shape something, can be defined as a document that indicates the place of an event within a timescale that has a particular start point (Akgür, 2010, 487). Calendars are usually arranged in relation to the movements of the two main celestial bodies, the sun and the moon. An Islamic calendar known as the Hijri Calendar was used by the Ottoman Empire from its foundation to its collapse (1299–1923). It was established in the period of Prophet Omer, based on the 36th–37th verses from the Quran's *Surah at-Tawbah*. In the hadiths indicated, it is written that the number of moons under the reign of Allah is 12. In the hadiths, it is indicated that a month lasts 29 or 30 days.

In the Hijri Calendar, the Hijri of Prophet Muhammad marks the beginning of the calendar, and the first day of the first month, Muharram, marks the New Year. This calendar, known as Hijri-lunar, is equal to 1 lunar year, 354 days, 8 h, and 48 min. The lunar year is approximately 11 days less than the solar year that the Gregorian Calendar uses today. Therefore, 33.5 Hijri years are equal to 32.5 Gregorian years. In other words, once every 33.5 years, the Hijri Calendar gets 1 year ahead of the Gregorian Calendar (Akgür, 2010, 489). Along with this inadequacy of the Hijri Calendar, it has another negative feature which is that it fails to comply with the seasons which have great importance in agricultural life (BOA, MV, 199/186; *Tasvir-i Efkâr*, 14 Mart 1329).

In Ottoman fiscal tradition, treasury incomes used to be collected according to the solar year and the expenses were consumed according to the lunar year (Sahillioğlu, 228). This operation continued smoothly in the period when the income-expense balance was kept; the incomes collected were well spent, and the Ottoman army was ruled without spending the treasury income (*Takvimü'l-edvâr*, 52–53). Another phenomenon that reinforced the system was the continuous expansion of the borders and, therefore, the increase in public revenues (Gemici, 55). The day difference problem between the lunar and solar year was solved by skipping 1 year once in every 33 years, and the year skipped was known *sıvış yılı* (Tezâkir, 110; Nevsâl-i Millî, 8).

The dissolution faced in the Ottoman manorial system (*timar sistemi*) disrupted the classical operation. In a period when the number of troops was increasing day by day, the salaries, which were paid four times a year, had become a great burden for the treasury. Moreover, the tax system that depended on real payments had been based on cash since the seventeenth century. Salary payments made in cash constituted 77 % of the government budget in 1630 and 62 % in 1670 (Barkan, 321–325). Delays in the payments led to uprisings initiated by the janissaries, and some of these uprisings occurred in the years following the skip period. In order to keep the income-expense balance, the government looked for

borrowing and devaluation. That meant a new tax and it affected the peasantry most. This chain of problems caused the peasants to leave their homes.

At the instigation of the head of the provincial treasury, Morean Osman Effendi, a new calendar known as the Financial Calendar, based on the Julian Calendar, was established in 1794, in order to solve the problem for the treasury arising from the day difference (Nevsâl-i Millî, 9). Because the name Julian was Greek, they tried to overcome the problem by using the Financial Calendar, also called the Julian Calendar, only in financial transactions after 1794 (Millî Nevsâl, 15–16). The starting date of this calendar, which was based upon the solar year and used in all official fields after 1840, was the Hijri of Muhammad (Ahmet Şakir, 25). The months' names were picked from ones used by the Assyrians and Romans (Gökdoğan, 91). Thus, an interesting calendar whose year digit was determined according to the lunar year, and whose month and day digit was determined in line with the solar year, was established. According to Ahmet Cevdet Pasha, whose studies drew attention to the subject of calendars, such a calendar had never been used by any other nation before 1582 (*Takvimü'l-edvâr*, 54–55). Meanwhile, Continental Europe preferred the Julian rather than the Gregorian Calendar which they had been using since 1582, and it was known as *Efrençî* by the Ottomans (Akgür, 1996, 71). Ottomans were familiar with this calendar from the Orthodox religion (*İkdam*, 18 Kanun-i sani 1332).

The move to start using the Financial Calendar for all official matters from 1840, which previously had been used only for financial transactions, was due to the centralization initiative of the Tanzimat Reform Era. Along with centralization, the number of troops, and through the developing bureaucracy, the number of officers was increased. An extraneous factor influenced bringing the subject of the calendar into question and from then on it never lost its importance. Because of the efforts of the Ottoman Empire, which gained speed after the Treaty of Balta Limani, they signed a compact with the United Kingdom in 1838, for unification with the capitalist world.

Executives of the Tanzimat Reform Era, especially Ali Pasha, took action with a number of pragmatic arrangements to create the prerequisite conditions for a capitalist economy. Hence, they took the European calendar, which had reached a certain standardization after the French Revolution, in exactly the same way, and the Ottomans also adopted the length and weight measuring systems. Ahmet Cevdet Pasha wrote a work entitled *Takvimü'l-edvâr* at the request of government executives, when it was deemed necessary to investigate the problem of how the dates fell. In this work, Pasha drew attention to the fact that the year 1288, which had escaped the attention of the executives and had been forgotten, was the skip year (Ma'rûzât, 206–207; Tezâkir, 109–110). The government bonds due to be issued in 1288 would be invalidated and that would cause trouble for the government and the courts (Şakir Paşa, 25; Islâhü't-takvim, 27). Warnings, especially from Ahmet Cevdet Pasha and the commissions that were working on the same matter, were not taken into account. The tradition was abandoned, and the final solution considered was to remove the sıvış yılı (BOA, YEE.KP, 86-35/3454; Ma'rûzât, 208).

It took time to integrate the Financial Calendar into daily life. In fact, in birth certificate applications brought after the Tanzimat Reform Era, the birth dates of some people were given based upon the Hijri Calendar, while some used the Financial Calendar (BCA, 030.10, 124.886.11; Uluçay, 136). In the year when the Financial Calendar was put into practice, postal services were also made open to the public (Eskin, 16). After almost half a century, in 1901, a small adjustment was made to this calendar by the Ministry of Post and Telegrams. In Europe, the day difference between the Julian and Gregorian Calendars was being discussed (The Times, 21 Oct. 1901). Because of the Ministry of Post's decision, the 1-day shortness in the Financial Calendar was increased to 13 days, which made it 584 years behind and 12 days shorter than the Gregorian Calendar. For postal transactions, it was decided that the months would be indicated by the number that referred to which month of the year it was, but not by its name.

Alongside changing the traditional units of measurement and weight, Tanzimat dignitaries intended to accept a new calendar system just like the Jacobins did in France, in order to make advances towards Europe (Kasaba, 20). However, not only were they unable to touch the calendar phenomenon reinforced by tradition and also the strong effect of religion associated with Hijri, but they were also going against the requests of congregations made in this direction.

Despite this, the Ottomans decided to use the same calendar which had been used in London, Paris, and Rome since 1910 and followed the congresses where the possibility of indicating time on a single scale was being discussed. The emphasis was placed on the positive effect of having only one calendar for the world economy, which would be used worldwide (The Times, 27 Oct. 1926). Wanting to act in unison with Europe, the Ottomans took action to regulate the calendar and the metric and hour system. They called this "putting the basis of amalgamation into practice" (Ergin, 264). The understanding of amalgamation would be taken in hand by the Financial Calendar (Nevsâl-i Millî, 9).

The Party of Union and Progress that steered government policies after the Second Constitutional Period did not have sufficient strength either to procure acceptance of the Hijri Calendar as the calendar for daily life, the Gregorian Calendar being the only calendar used in relations with Europe even unofficially, or to remove the Financial Calendar (Takvimü's-sinîn, XX) which was deemed necessary to abandon by the leading experts. The party sought reformation only, but on 22 September 1911, this was rejected by the Council of State, on the grounds that the attempt to accept it as the beginning of the year would lead to confusion (BOA, MV, 124/66).

The Financial Calendar was criticized, as its origin was the same as the one used by the Slavs who gained their independence following the Balkan Wars. Thus, the Financial Calendar, which was the one used by the enemies, was once again brought onto the agenda in the second year of the First World War. At that time, the Ottoman armies were fighting their enemies in Galicia, Macedonia, and Palestine, and

communication and contact with the allies were gaining importance in order to avoid confusion. When using the main means of communication, telegrams, not only was it necessary to use the same language as the allies but also to indicate the same date they used. Meanwhile, the old enemy but the new ally, the Bulgarians, had accepted the calendar that was used by Western countries (*The Times*, 29 March 1916).

The government's intention was to make up the difference of the 13 days between the Financial and Gregorian Calendars. When the government asked for such a change, it also made clear that the birth of Christ would never be accepted as the beginning point of the calendar (1332–1333..., 358). When the matter was brought to the agenda of the parliament, Mr. Talat, Minister of the Interior and Treasury, who spoke on behalf of the government, reminded them that the Hijri Calendar had not been tampered with. He also said that the government's intention was to make up the difference of 13 days and to take the beginning of the year as January. He finished his speech by stating that the state treasury would make a profit of 180,000 liras after this change, and it would also make a loss at the same rate if the change was not brought about (MMZC, 11 Şubat 1331, 124–145). However, a few days later, the government, unable to obtain what it had asked for from the parliament, announced that it had revoked the law.

As well as the Hijri and Gregorian Calendars, all other calendars take their holy dates as the starting point. The Ottomans went further in that they considered the 1300s sacred. That is to say, when the government raised the question of the calendar once again, it was discussed in parliament whether the year digit would be indicated by the 1300s or 1900s. The problem was resolved with the notion that the 1300s belonged to the Nation of Islam (*Tasvir-i Efkar*, 1 Mart 1333), and for this reason, the 1300s continued to remain on the calendar.

The discussions continued for a year, ending with a law that came into effect on 8 February 1332. The Financial Calendar was abolished and the Gregorian-based Western Calendar started to

be used (BOA, İDUİT, 87/22). By skipping 13 days, 1 March 1333 followed 15 February 1332. The year of 1333/1917 started from 1 March and lasted 10 months, with the next year, 1334/1918, starting as of 1 January (Takvimü's-sinîn, X; *Tasvir-i Efkâr*, 1 Mart 1333). With the new regulations, 2 months and 16 days were missing from the year 1917. In the period when the expenses were increasing during war time, the government budget gained much more importance. The issue of how the gap caused by the period skipped from the year 1917 could be filled was resolved thanks to certain guarantees given (BOA, MV, 205/141; DH.UMVM, 1/53). As such, the government guaranteed that there would be no problem with extracting taxes and rents and with the tax-farming contracts. Also, the regulations did not deeply affect people's daily lives although there were minor inconveniences in the official business of the citizens and the provincial administration had a little difficulty in adopting January as the beginning of the year.

The necessity of determining the equivalents of certain days in the new calendar was raised by a German diplomat's question on whether the sultan's ceremony of accession was changed or not (BOA, DH.İUM, E30/29; DH.UMVM, 124/101). In those days when the press also helped the community, several associations drew attention to their work. For instance, it was important that the Mûdafaa-yı Milliye Cemiyeti had wall calendars prepared based on the Western Calendar. On these new wall calendars, sections indicating the religious dates were included. However, a few years later, as with the wall calendars, it was discovered that the dates indicated in pocket and desk calendars had not been determined correctly by the Office of the Chief Astronomer (Müneccimbaşılik). In the final days of the empire, it was discovered that the Office of the Chief Astronomer had not exercised the necessary controls and, more precisely, had neglected its duty (BOA, DH.İUM, 19-18/1-38).

The reaction against the Western Calendar broke out due to a combination of the Party of Union and Progress (İttihad ve Terakki Cemiyeti) and the resentment felt towards its leaders. At the

beginning of the year 1920, the *Tasvir-i Efkâr* newspaper that had previously written on the issue of procuring society's acceptance of the new calendar now appeared before the society with a quite different discourse. The newspaper reportedly found the calendar change meaningless and strange, made by the Party of Union and Progress hurriedly during the war. The paper also regarded the acceptance of the New Year start date as the product of "wise-guy brains" (*Tasvir-i Efkâr*, 1 Kanun-i sani 1336).

In fact, the newspaper reflected the views of society, whose voice had not been heard until then. British and French hostility increased after the Armistice of Mudros, applying to almost anything that belonged to them, and also for the Gregorian New Year. Therefore, although the new year of the Hijri had not been celebrated in previous years, in the period of armistice, it started to be celebrated with nostalgia, with a religious emphasis added to it. In contrast, the Muharram, the first month of the year of Hijri, reminded the Muslims of the Karbala Incident, during which Hussain, the grandchild of Prophet Muhammad, was murdered (Akçura, 36). In the celebrations of the New Year of Hijri that took place at the end of the war, the longing felt for Islam, the period before the Party of Union and Progress, meant that this historical event was discounted. Thus, the high state officials appeared before the sultan and participated in the official New Year ceremony (*Tasvir-i Efkâr*, 27 Eylül 1335).

With the aim of modernization, the executives of the Turkish Republic, which was founded in 1923, were able to take the radical decision to deal with the Hijri Calendar. The developments occurring outside Turkey were also effective in supporting their cause. The League of Nations wanted to create a global calendar by making a calendar reform by means of commissions it had established (*The Times*, 27 Aug. 1923). As, in the Gregorian Calendar, the number of days in the months were not equal to the quarter and half periods of the year, but for the sake of convenience in commerce, industry, transportation, and communication, it was required to stabilize these periods (*The Times*, 27 Oct. 1926). The attempt of

the League of Nations remained inconclusive, but the Turkish executives, who followed the reform exercises closely, did not hesitate in accepting the Gregorian Calendar.

By enacting a law into practice, dated 26 December 1341/1925, the calendar problem that had persisted since the Ottoman period was resolved. The Calendar of Garbi was revoked by the law specified, and the Gregorian Calendar started to be used under the name "International Calendar" as of 1 January 1926. Usage of the Hijri Calendar was restricted, and its use was approved only when determining the sacred days and months (Üçer, 122). In justifying the decision of the law, it was written that the Western Calendar (Takvim-i Garbî), which did not have any scientific foundation, was erroneous and the sacred days would be determined based on the Gregorian Calendar, in accordance with the technical principles of the observatory (Öztürk, 106–107).

When the law was brought to the agenda of the Turkish Grand National Assembly, some members of the parliament were vocally opposed. However, compared with the strong opposition of the Ottoman Parliament and the members of notables, this group remained a minority. Such opposition seen in the parliament was barely apparent in the press, which supported the "Calendar Revolution" unconditionally. Thanks to this law, a step was taken towards westernization and the new Turkish Republic would proceed on its way by removing a calendar, which was a thing of the past. In the meantime, the Hijri Calendar, which had been identified with the Ottoman Empire, had its share of criticism (*Cumhuriyet*, 1 Kanun-i sani 1926).

The new calendar brought to Turkey the tradition of celebrating the New Year in the European style. New Year celebrations took place on the night between 1926 and 1927, attracting great attention, and the celebrations lasted all night long. Also for the first time, on that night the power administration started the tradition of turning off the city lights in Istanbul for a minute at exactly 12 o'clock (Tuna, 41–49).

The latest development on the matter of the calendar was the alteration of the names of the

months. The process of changing the names of the months was initiated in the course of translating the Constitution of 1924 into Turkish in 1945. The names teşrin-i evvel/birinci teşrin, teşrin-i sani/ikinci teşrin, kanun-i evvel/birinci kanun, and kanun-i sani/ikinci kanun were replaced with Ekim (October), Kasım (November), Aralık (December), and Ocak (January), respectively.

Caraka

Guy Mazars

Caraka is the editor of a treatise of Āyurveda which bears his name, the *Carakasamhitā* or “Caraka’s Compendium”, a work with which classical Indian medicine really begins. The *Carakasamhitā* is supposed to contain the teaching of the sage ► **Ātreya** Punarvasu, recorded by one of his disciples, Agniveśa, and revised by Caraka. Ātreya and Agniveśa belong to the realm of legend, but Caraka is likely to have been a historical figure. Indeed, according to the Chinese version of a Buddhist text, translated from Sanskrit in the fifth century AD, a physician of the same name was practising at the court of the Scythian king Kaniška. Several scholars place this king at the end of the first or second century AD. Like Aśoka (264–227 BCE) some centuries earlier, Kaniška was well disposed towards Buddhism and protected it. During his reign, Indian culture underwent a great expansion. The redaction of the *Carakasamhitā* thus goes back to this period, if it is indeed the same Caraka.

However, the text which has come down to us is a composite work. It contains more recent portions added at the time of its revision by an author from Kashmir, Dṛḍhabala, who probably lived in the fifth century AD. But the core of its content is much older since Caraka himself had only reconstructed an already existing work, cited under the name of *Agniveśatantra*, the “Book of Agniveśa”. At least one of the redactors of the “Compendium” was familiar with the diets

and habits of peoples from different parts of the world. The *Carakasamhitā* was commented upon before the ninth century by Jejjāṭa, who may have been a Kashmirian or an inhabitant of Sindh. Then, in the eleventh century, Cakrapāṇidatta wrote a commentary called *Āyurvedadīpikā*, which has been preserved and edited. Cakrapāṇidatta was a native of Bengal, himself the author of the *Cikitsāsamgraha*, a well-known manual of therapeutics. He wrote other works, including the *Dravyaguṇasamgraha*, a short treatise of materia medica. According to the Arab bibliographer Ibn an-Nadīm, in his *Kitāb al-Fihrist* (Index of Arabic books, completed in 988 AD), a Persian version of the *Carakasamhitā* had been translated into Arabic by the time of the first ‘Abbāsīd caliphs (eighth century).

In its present form the *Carakasamhitā* consists of 120 chapters which are divided into 8 parts (*sthāna*):

1. Thirty chapters in the *Sūtra* section dealing with various topics, including pharmacology, diet, some diseases and their treatments, physicians and quacks;
2. Eight chapters in the *Nidāna* section dealing with the causes of eight main diseases;
3. Eight chapters in the *Vimāna* section dealing with different topics such as “taste”, logic, vessels, pathology and medical education;
4. Eight chapters in the *Śārīra* section dealing with embryology and anatomy, and on the connection between the body and the mind;
5. Twelve chapters in the *Indriya* section devoted to diagnosis and prognosis;
6. Thirty chapters in the *Cikitsā* section dealing with therapy;
7. Twelve chapters in the *Kalpa* section on pharmacy; and
8. Twelve chapters in the *Siddhi* section devoted to general therapy.

Cashewnut Processing on the Malabar Coast

K. T. Rammohan

The cashewnut processing industry on the Malabar Coast grew around the port towns of Quilon, Calicut and Mangalore, which had cashew-growing hinterlands. Cashew was not a systematically cultivated tree crop. In earlier days, poor people gathered the nuts, roasted them in mud pans, removed the shells by hand and sold the kernels in nearby markets. From the early decades of the twentieth century, trading companies from the West operating on the coast began to purchase shelled kernels from local people for export. After sun drying, cashew kernels were packed in mango wood cases lined with newspaper and shipped out, mainly to Marseilles and occasionally to London from where these would be re-exported. From the 1930s, with the emergence of the United States as a major buyer, the industry gained substantial momentum. To meet the increased demand, the trading companies resorted to the putting out system of production. The companies bought raw nuts locally (and also imported nuts from East Africa) and distributed these to people, who pan-roasted

and returned the shelled kernels to the company. The kernels were dried, peeled, graded and packed at the company premises. Later, as the putting out system gave way to direct production by firms, factories where all the operations were undertaken emerged. The factories employed women and children of lower castes and outcastes who were paid very low wages. Over 90 % of the workers were women. Men, again drawn from lower and depressed castes, were engaged primarily in roasting.

Cashewnut processing involved five principal operations: roasting, shelling, peeling, grading and packing. In the early factories roasting of nuts was done in the open air in iron pans. From 1932, iron pan roasting was replaced by drum roasting. Under the new method, an open-ended drum (rotary cylinder) was placed over a fire in a tilted position. Raw nuts were fed from one end, and roasted nuts were collected from the other. Each cylinder needed six persons to operate: the first person attended to the furnace, the second and third fed the raw nuts, the fourth rotated the cylinder, the fifth removed the roasted nuts, and the sixth sprayed water on the roasted nuts. The workers wrapped themselves in gunny bags to protect themselves from burns. By the mid-1930s, hot oil roasting replaced drum roasting. Here, raw nuts were roasted in a bath of cashew shell oil maintained at about 200 °C. Due to the high temperature, the oil cells of the nuts broke, releasing their contents; and the nuts were then roasted to the desired degree. Cashewnut processing yields a by-product – cashewnut shell oil that has industrial and strategic uses. This could be extracted in full only in oil-bath plants. All these methods used cashewnut shells as fuel.

After roasting the nuts were shelled. This was the most arduous operation and had to be done in an uncomfortable squatting posture. Nuts were placed on a flat stone and were gently hammered with the help of small wooden mallets, to remove the shells. A high degree of skill was required to ensure that the kernels did not break. Peeling the skin off kernels was also a dexterous, repetitive and loathsome task. The kernels were then graded and packed.

Cave Architecture of India

Pia Brancaccio

Department of Art and Art History, Drexel University, Philadelphia, PA, USA

Caves in ancient India were places of special relevance. Aside from offering natural shelter, they were regarded as *loci* of supernatural powers and spiritual enhancement. Located at the *nexi* of sacred geographies and often associated with local deities, caves were favored abodes by hermits and renouncers. Elaborate rock-cut architectural structures were created for ascetics to use during the Maurya period (322–185 BCE) with King Ashoka (304–232 BCE) being the first to endow man-made caves to the Ajivika ascetics at Barabar Hill (Falk 2006). The four Barabar caves located in a rocky outcrop in the Gaya district of

Bihar preserve distinctive plans with rectangular spaces attached to a circular, hut-shaped room at one end. The cave interiors are plain and flawlessly polished in a manner that alters light and sound. The only decoration appears at the entrance of the so-called Lomas Rishi cave where a portal motif with an architrave embellished by elephants and *stupas* is engraved in the living rock (Fig. 1).

During the second and first centuries BCE, rock-cut structures for ascetics were also created in Orissa in the Udayagiri and Khandagiri hills (Mitra 1975). These caves consist of simple series of cells with decorations above the entrances representing trees, elephants, and figures reminiscent of types seen in Shunga terracotta plaques. The Hathigumpha cave at Udayagiri carries a famous inscription by the local king Kharavela. From this time onwards, simple rock-cut complexes also began to develop in Gujarat, in a prosperous area involved in long-distance trade where both Jain and Buddhist religions thrived. The early caves at Junagadh, among others, include simple cells opening on porches with minimal ornamentation that takes the form of auspicious emblems (Soundara Rajan 1985).

Between the second century BCE and the second century CE, a surge in Buddhist patronage led to the establishment of many Buddhist rock-cut sites in Maharashtra along the western edge of the Deccan Plateau (Dehejia 1972; Dhavalikar 1984). These excavations were large and elaborate and typically included monastic residential caves along with an apsidal hall destined for worship (Burgess and Fergusson 1988). Called *chaitya-griha* or *chaitya* hall in the votive inscriptions, this sacred space presents a row of columns running parallel to the walls and a rock-cut stupa placed at its end. The caves at Bhaja were among the earliest in western Deccan (second to first c. BCE): the *chaitya* hall was finished with wooden elements such as beams inserted in the rock vault and a wooden façade now missing, and rock-cut images of arches and balustrades with *mithunas* or couples frame the entrance. The monastic residences at Bhaja consist of series of cells equipped with stone beds;

Cave Architecture of India, Fig. 1 (a) Lomas Rishi cave, general view and (b) entrance to the cave (By Harry Falk)

Cave Architecture of India, Fig. 2 (a) Bhaja, *chaitya* hall, and (b) cave 18

they open on small rectangular porches, generally undecorated, with the exception of cave 19 where carved in low relief are royal figures riding an elephant and a horse-pulled chariot, previously identified as the Vedic gods Indra and Surya (DeCarolis 2000). Buddha images do not appear in the early caves of western Deccan (second c. BCE–second c. CE) generally associated with the Hinayana tradition, and the figural decorations in this phase consist mostly of images of *mithuna* or couples such as those at Bhaja or guardian *yakshas* like those at Pitalkhora (Figs. 2, 3, and 4) (Deshpande 1959).

Buddhist cave architecture in western Deccan soon emancipated itself from the use of wood, and most *chaitya* halls came to be entirely carved out of living rock. The *chaitya* hall at Karle has an ornate stone façade and an interior with elaborate pillar bases and capitals, while the Ajanta *chaitya* hall no. 10 was embellished by vivid paintings (Schlingloff 1987). Sometime during the first century CE, well-planned monasteries, with rock-cut cells aligned along three sides of a square court, were introduced in Buddhist cave architecture; caves 3 and 10 at Nasik bearing inscriptions of the Kshatrapa king Nahapana and

Cave Architecture of India, Fig. 3 Pitalkhora, Yaksha

the Satavahana rulers constitute excellent examples of such square *vihara* cave types (Fig. 5) (Bhandare 2006; Rees 2009).

Buddhist rock-cut monasteries in western Deccan were often supported by gifts of traders and craftsmen, as suggested by in situ votive inscriptions (Burgess and Indrajī 1976), and the sites benefited from the wealth brought to the area by thriving Indian Ocean trade (Ray 1981). The caves, called *lena* in the inscriptions, grew in clusters around important passes along the edges of the plateau (Sahyadri Range), near trading routes (Chakraborti 2005; Lahiri 1992), not too far from urban centers, and often in areas where agricultural land was readily available (Brancaccio 2010). The Buddhist caves at Bhaja, Karle, and Bedsa were grouped along the

Cave Architecture of India, Fig. 4 Karle, *chaitya* hall

Bor Ghat pass; the large four clusters of caves at Junnar (Tuljalena, Manmodi, Shivneri, and Lenyadri) overlooking fertile land were also situated in proximity of the Nanaghat pass. The caves at Pitalkhora, Ajanta, and Aurangabad were strategically located along major internal trade routes, while in coastal Konkan flourished the Kondivte, Kuda, and Kanheri caves. The latter, located near the ancient port of Kalyan, experienced an unusually long period of activity (Ghokale 1991; Ray 1994). Stylistically related to the earliest Buddhist sites in western Deccan are also the caves at Guntupalli in Andhra Pradesh (ca. second c. BCE) that include a round *chaitya* hall similar to the one from Kondivte in Maharashtra (Brancaccio 2013).

The fifth century marked a renewed interest in patronage of rock-cut architecture in northwestern India. Most relevant are the Vaishnava caves at Udayagiri in Madhya Pradesh realized under the Gupta dynasty (Willis 2009) and the major

Cave Architecture of India, Fig. 5 Nasik, caves 3 and 10, plans after Gethin Rees, <http://www.ancient-asia-journal.com/article/view/aa.10209/47>

Cave Architecture of India, Fig. 6 (a) Ajanta, *chaitya* hall 26, and (b) cave lower 6 (By Nicholas Morrissey)

expansion of the Buddhist caves at Ajanta undertaken by the Vakataka king Harishena and his entourage (Spink 2007-14). At Ajanta two more *chaitya* halls and 20 additional *viharas* (monasteries) were created at the end of the fifth century, and they were all embellished by elaborate paintings of *jatakas*, *avadanas*, and other Buddhist images that survive only in part (Schlingloff 1988; Jamkhedkar 2009; <http://www.ajantastudygroup.com/>). By this time the Buddha image had become the focus of worship at Ajanta: aside from sculptures on *chaitya* halls stupas, each *vihara* at the site included a cell with

a larger than life sculpture of the Buddha seated on a throne placed on axis with the entrance (Schopen 1997). Buddhist patronage continued well into the sixth century at the nearby site of Aurangabad where new architectural layouts were developed. Smaller caves were created, with or without side cells, that included a square central shrine with a Buddha image surrounded by a corridor for circumambulation as in caves no. 2, 5, 7, and 8 (Figs. 6 and 7) (Brancaccio 2010).

Buddhist caves in western Deccan experienced a slow decline beginning in the sixth

Cave Architecture of India, Fig. 7 (a) Aurangabad cave 2, view and (b) plan

Cave Architecture of India, Fig. 8 Sadashiva at Elephanta

Cave Architecture of India, Fig. 9 Ellora, cave 29, Dhumarlina

century, as patronage in the region shifted to the creation of Shaiva rock-cut temples (Tarr 1969; Soundara Rajan 1981) – most notably the ones at Elephanta in Konkan and at Ellora in the Aurangabad district. The unfinished great cave or cave 1 on the Elephanta Island took rock-cut architecture to monumental proportions with its huge, rectangular hall including colossal pillars, multiple points of access, as well as *linga* shrines (Spink 1982; Michell 2002; Dhavalikar 2005). Elephanta cave 1 is best known for the monumental relief of a three-headed Shiva (usually labeled as Sadashiva) dominating the south wall (Fig. 8) and for the large tableaux depicting other forms and feats of the god carved on the

remaining rock walls (Collins 1988). It is also during the early sixth century that a first group of caves dedicated to the god Shiva was established at Ellora (<http://elloracaves.org/>). These excavations are stylistically linked to the

Elephanta cave as exemplified by cave 29 also known as Dhumar Lena (Spink 1967). It is not until the eight century, after more Buddhist caves had been cut on the southernmost edge of the

Cave Architecture of India, Fig. 10 Ellora, cave 17, Kailash temple (By Lisa Owen)

Ellora cliff (caves 2–12) (Malandra 1993), that the spectacular rock-cut Kailash temple (cave 16) was created under the Rashtrakuta king Krishna I (Dhavalikar 2005). This rock-cut structure is covered by elaborate carvings and echoes the shape of Shiva's mountainous abode (Brancaccio 2013); it stands completely free from the rock cliff, where multistoried pillared halls and rectangular chapels are excavated all around. In the ninth century Ellora was also occupied by the Jains who cut a few more elaborate caves (caves 30–34) on the northern edge end of the site (Figs. 9 and 10) (Owen 2012).

The Deccan was the heartland of cave architecture, and the Chalukya kings continued the tradition of rock-cut temples at Badami and Aihole in Karnataka, where caves were cut between the end of the sixth and the eighth century (Srinivasan 1964). The four Badami caves, three Hindu and one Jain (no. 4), have simple layouts that include a shrine, a rectangular pillared hall embellished with sculptures, and a porch or *mandapa*. They seem to be stylistically related to the earliest Hindu caves at Ellora; in particular, Badami cave 3 dated by an inscription to 578 is akin to cave 21 at Ellora (also called Rameshvara (Tarr 1970)) (Fig. 11). The small Ravana Phadi cave dedicated to Shiva at Aihole seems to bridge, in terms of style and design, the

Cave Architecture of India, Fig. 11 Badami, cave 3, porch

Cave Architecture of India,

Fig. 12 Mahabalipuram, Arjuna, and Draupadi Rathas

rock-cut tradition of the Deccan with that of Tamil Nadu.

Under the Pallava dynasty cave architecture blossomed in Tamil Nadu, along the southeast coast of India. The most impressive are the Hindu caves and monolithic rock-cut temples at Mahabalipuram dating to the seventh century CE (Nagaswami 2011). The caves are many and modest in size; they generally include a shrine that opens directly onto a small porch embellished by sculptures of Hindu gods. The most remarkable are the so-called Varaha, Trimurti, and Mahishasuramardini caves. Among the nine freestanding monolithic temples, five are clustered together and are known today as the five Rathas. These unfinished monuments replicate different building types in the living rock, and the four that appear to be aligned (the so-called Draupadi, Arjuna, Bhima, and Dharmaraja) were originally carved out of a single boulder. Each temple, dedicated to a different Hindu god, is intricately carved on the outside and is associated with a sculpted *vahana* or divine animal; the interiors are barely roughed out or simply unfinished (Fig. 12) (Dehejia and Davis 2010).

Celestial Vault and Sphere

Cornelis Plug

University of South Africa, Pretoria, South Africa

The celestial vault is the apparent surface of the sky – both the night sky against which the stars appear to be placed and the blue expanse of the daytime sky. This surface may be assumed to be either imaginary or real and in the latter case is commonly referred to as the *firmament*.

The idea that the celestial vault, and particularly the daytime sky, is a physical cover of some kind is found in the cosmologies and myths of many cultures. In sub-Saharan Africa, a widespread belief is that the daytime sky is a solid blue vault resting on the earth, on which the sun moves. During the night, the sun is thought to return to the east by passing either under the earth (e.g., the Luyia of Kenya) or behind the solid sky (e.g., the Zulus of South Africa); in the latter case, it also produces the stars by shining through small holes in the vault. The idea that the sky is a solid surface was also commonly accepted in China, India, among American Indians, and Australian aborigines. Ethnic groups in northern Eurasia thought of the sky as a roof to protect the earth and life and often described it as resting on a central pillar. In the hero tales of the Yakuts, the sky was said to be hemispherical, resting on the outer edge of the world. In the mythologies of Finland, Lapland, and neighboring regions, the celestial pole or the pole star was described as the “nail of the sky” which supports the celestial vault and around which it revolves. The Lapps, Finns, Yakuts, Japanese, and Hebrews sometimes described the sky more specifically as a tent roof. The most popular conception of the sky in ancient Egypt was that of a blue-water surface, a continuation of the sea or the Nile. Similar ideas were applied to the night sky. The Milky Way appeared to some as a stitched seam, and the stars as tiny holes in the fabric of the celestial vault.

The large amount of attention given to the nature of the celestial vault in cultures all over the world seems to stem mainly from its perceived function as a substratum on which the celestial bodies are situated or upon which they move. The celestial bodies and their movements, and to a lesser extent the celestial vault itself, were of absorbing interest to people in all cultures for a variety of reasons, both practical (e.g., as a basis for the calendar and agricultural practices), magical (e.g., predicting future events), social (regulating social events), and religious (e.g., believing the celestial vault, or the space behind it, to be the home of the gods). Among many native tribes in Colombia, for example, “the sky is seen as an enormous blueprint of everything that did, does, or will happen on the earth; a map replete with information on every aspect of biological and cultural behaviour” (Reichel-Dolmatoff, 1982, p. 165). This information is thought to have provided the people with a measure of security. Furthermore, the diurnal cycle of the celestial vault, coupled with the regular appearance and disappearance of the sun and stars, may have instilled by similarity belief in rebirth and the transcendence of death (Belmonte, 2010).

Although the perceived solidity of the celestial vault implied a fixed form for the sky, that form was seldom clearly defined. There was some debate among early astronomers in China on whether the celestial vault might be strongly flattened, perhaps even a plane parallel to the earth’s surface. For example, the astronomical chapters of the official history of the Chin dynasty (265–420 AD), written in the seventh century under the supervision of Emperor T’ai Tsung, contain a discussion by the scholar Ge Hong (previously spelled Ko Hung [283–343]) of the theory that the sun cannot be seen at night because it moves a great distance away from the earth. Ge Hong argued (Ho, 1966, p. 57): “If it is said that the sun can no longer be seen because it has gone a very great distance from us, then when the sun sets, on its way towards the north, its size should diminish. But, on the contrary, the sun becomes larger at sunset.” This refutation of the flattened vault theory did not originate in China. It was stated in similar words by the Greek

astronomer Claudius Ptolemy in the *Almagest* (Book 1, chapter 3), written around 142 AD. The similarity of the wording leaves little doubt that intellectual contacts existed between China and the Middle East at the time.

The idea that the celestial vault is actually flattened has been ascribed to Empedocles, a Greek philosopher of the fifth century BC. Ptolemy’s refutation of the theory was later transmitted to Islamic scholars as part of the *Almagest* and was slightly elaborated by the astronomer al-Farghānī in the ninth century. However, by this time, most astronomers had accepted that the celestial vault represents the upper half of an imaginary (or sometimes real) spherical surface (or a set of concentric surfaces), called the celestial sphere, which carries the stars. The other half of this sphere is below the horizon. Celestial spheres were key elements in the cosmological models of Aristotle, Plato, Ptolemy, Copernicus, and others. These authors saw the stars and planets as being embedded in rotating, concentric, transparent spheres. Others regarded all the celestial bodies as moving on the same sphere, with the exception of meteors. Arab philosophers regarded meteors as occurring in the terrestrial environment rather than on the celestial sphere.

Irrespective of the assumed shape of the celestial vault, the apparent positions, sizes, and movements of the sun, moon, planets, comets, and stars have often been described as if these bodies are situated on a real surface. Estimates of the sizes and separations between the celestial bodies were therefore expressed as lengths or distances on the celestial vault rather than in terms of angles. For example, Chinese observations of comets from the second century BC to the nineteenth century were expressed in terms of the *zhi*, a length standardized as 311 mm in the ninth century. The *zhi* appears to have corresponded to an angle of a little less than 1°. Similarly, the Babylonian *ammāt* (about 524 mm) represented either 2° or 2.5° at different times. And the Islamic *fitr* and *shibr* (spans later standardized as 152 and 178 mm, respectively) were equivalent to about 0.6° and 0.8°, respectively, in the astronomical work of Ibn Yūnūs during the eleventh century.

These lengths and angles seem to imply that the astronomers in each of the three cultures assumed that the celestial sphere had a radius of only some tens of meters. Numerous estimates of the perceived sizes of the sun and moon (usually seen as some 200–300 mm across) from classical to modern times in Europe support the same conclusion: there exists a universal tendency to describe perceived sizes and distances on the celestial vault as if the height of the sky is only a few tens of meters.

Although astronomers had long rejected the idea that the celestial bodies move along flattened trajectories, the Islamic physicist Ibn al-Haytham pointed out in the eleventh century that the sky usually *appears* flattened. He explained this as an illusion created by our perception of distant objects toward the horizon and the lack of such indicators of distance toward the sky. He furthermore used the flattened appearance of the celestial vault to explain the illusion that the sun and moon are enlarged near the horizon – an explanation that was transmitted to Western Europe during the thirteenth century and survived well into the twentieth century. Its importance lies in the fact that, for the first time, the perceived flattening of the celestial vault and the perceived enlargement of the horizon sun and moon were described as perceptual illusions (now studied by psychologists) rather than measurable phenomena to be studied by astronomers.

Pottery making is a very ancient craft in Africa, as some of the oldest pottery remains known in the world were discovered on this continent. Dating from around 10,000 BCE – i.e., one or two millennia after the inception of the Jomon pottery in Japan – they were excavated in the Aïr Region of Niger (West Africa) (Haour, 2003).

Throughout history, the craft has endured important changes in relation to the shape, function, and decoration of the products, as well as manufacturing techniques, scale of production, or the social status of the potters. The last decades have proved particularly significant in that

regard, due to the massive introduction of plastic and metal containers, social and economic transformations, the development of tourism and urban lifestyle, and the spatial extension of social networks. In most places, ancient pottery functions such as cooking, handling, and serving have been abandoned, while new categories of products such as decorative or commemorative items, flowerpots, tiles, braziers, or incense burners have boomed. Water jars, however, continue to be massively produced in some parts of the continent, as they provide the cheaper and most efficient way of keeping cool water in rural areas.

Social Background

A comparison of several hundred ethnographic sources (Information examined in this article comes from two bodies of data. Since 1990, members of the *Ceramic & Society Project* developed at the University of Brussels and its research associates have conducted fieldwork in Senegal, Gambia, Mali, Niger, Burkina Faso, Togo, Benin, Nigeria, Cameroon, Chad, and D.R. Congo, collecting information about some 1,000 potters in nearly 100 linguistic groups. The second body of data comes from a systematic perusal of the ethnographic and ethnoarchaeological literature devoted to pottery making in sub-Saharan Africa. These sources are of varying relevance and accuracy as they range from large-scale and detailed studies to more local/regional observations, or mentions in ethnographic monographs, administrative reports, and religious publications. Altogether, more than 900 sources have been processed, which relate to some 650 linguistic groups.) indicates that at last four-fifths of the African potters working today are women, which confirms the usual description of pottery making in Africa as a “female activity.” But male potters are also encountered in several regions of the continent, where they either specialize in the making of particular vessels (big water jars, elite ware, bottles) while women produce the largest part of the repertoire, or produce the whole range of vessels in contexts where women are excluded from the

craft, or work together with female relatives, carrying out specific operations such as clay extraction and transport, clay preparation, firing, and, above all, plastic decoration (Schildkrout & Keim, 1990).

The scale of production is highly variable, ranging from part-time, isolated artisans, whose products are essentially consumed locally, to full-time specialists working in workshops, whose vessels are distributed by middlemen in a 100–200 km radius. If men tend to be more frequently associated with the latter category, female potters may also be involved in mass production, especially in West Africa.

In many instances, pottery making is open to anyone. All one has to find is someone who is willing to serve as a teacher. This means, in practice, having a close relative, friend, or neighbor who engages in pottery making and does not mind spending time with someone who may subsequently become a competitor. But restrictions are also observed throughout the continent, which pertain to age, gender, geographical origin, and, above all, socio-professional affiliation. For example, in many Sahelian societies, potters belong to caste-like subgroups such as blacksmiths, bards, tanners, weavers, woodcarvers, hunters, or jewelers (Drost, 1968; Frank, 1998; Gallay et al., 1998; Gosselain, 2001; Haaland, 1978; Lyons & Freeman, 2009; Sterner & David, 1991, 2003; Tamari, 1997). The members of these endogamous specialist groups are associated with specific activities and duties and distinguished from the remaining population. They are regarded with a mix of awe and contempt by nonspecialists, who often consider them dirty and impure and fear being harmed by their power. Due to recent economic changes, however, caste-like structures may become permeable to other social groups in specific places.

Manufacturing Process

There are seven main stages in the pottery manufacturing process: (1) clay extraction, (2) clay processing, (3) shaping, (4) decoration, (5) drying, (6) firing, and (7) postfiring. While

most of these stages are mandatory, some – such as decoration and postfiring – are optional, although widely recorded across the continent (previous surveys of pottery manufacturing processes in Africa include Devisse, 1984; Drost, 1967; Gosselain, 2002; Krause, 1997; Livingstone–Smith, 2007).

Clay Extraction

Available data indicate that most African potters collect their clay within a 3-km radius from the place where they live and/or practice the craft (see Gosselain, 2002, pp. 40–41). Those who exploit sources beyond this threshold generally use animals, cars, trucks, or canoes to carry the clay. They also tend to make stocks that last from several weeks to the whole potting season.

Four categories of extracting techniques are observed in Africa: surface collection, pit extraction, underground gallery, and underwater extraction.

In surface collection, clay is extracted on or just below the surface, either on the ground (plain, fields, dried ponds, or riverbeds), a hill, or the wall of a slope or an embankment. After having eliminated the superficial organic and mineral layer, the potter extracts clay without really digging underground. The operation may be described as “peeling” a clay bed.

In pit extraction, potters dig vertically or diagonally into the ground, until an appropriate layer is reached. Most pits are some 1 or 2 m deep and 2 or 3 m in diameter. Due to repeated and intensive exploitation, they may take the form of a quarry, as in southeastern Nigeria (Nicklin, 1979, p. 349). Variations are observed in the way potters exploit and manage these structures. For instance, some use a pit until the clay layer is completely exhausted, while others abandon it when a specific depth is reached or as soon as it shows risks of collapsing.

Raw materials may also be extracted from galleries. This type of structure generally starts with the excavation of a vertical shaft. When the access shaft reaches the clay bed, the structure is extended horizontally (Livingstone Smith, 2007; Nwafor, 1980; Schneider, 1993). Galleries, like

pits, are generally abandoned at the end of the potting season, but some may be used several years in a row, the access shaft being re-excavated each year.

Finally, a rather uncommon technique consists in extracting clay from the bed of an active river, as among Tikar of Cameroon and Punu of Gabon (Gosselain, 2002, pp. 52–53). Here, artisans build two small dams in the river, bail out the water contained between the dams, and extract clay before the upstream dam gives way.

It is usually in the course of other activities, and especially activities which force them to dig into the ground (e.g., tending fields, building houses, digging wells) or to frequent places such as riverbeds or swamps, that potters, members of their family, or any of their acquaintances may discover a new source and get the process leading to its possible exploitation under way. This involves assessing both the intrinsic qualities of the material (which often includes firing test vessels) and the compatibility of the site with other imperatives.

A first requirement is that the clay must have the right physical properties, i.e., its plasticity, texture, color, and even taste and odor must fit with a potter’s personal requirements (see also Barbour, 1989; Brown, 1989; Frank, 1998; Trowell, 1941, p. 61; Woods, 1984, p. 305). If newly discovered clay is judged suitable, a second requirement is that it must be located nearby the potter’s main occupational areas and/or working place. Since pottery making is often subordinated to other activities – such as farming and domestic tasks – potters tend to restrict their investment in time and energy or, at least, avoid scheduling conflicts when practicing the craft. Sources located nearby living or working sites, fields, rivers frequented for fishing, roads, or tracks are therefore more likely than others to be selected and subjected to long-term exploitation. In fact, about 90 % of the hundreds of sources that we visited in sub-Saharan Africa were situated nearby or within sites used primarily for other activities. Such a situation has an obvious impact on clay exploitation strategies. More importantly, it shows that clay extraction sites are not distributed randomly or according to

a craft-specific logic but are fully integrated in the territory frequented by both potters and non-potters.

Finally, rituals and taboos often surround the selection and exploitation of clay sources (Barley, 1994; Berns, 1993; Drost, 1964; Gosselain, 1999; Herbert, 1993; Pinçon, 1993). For instance, certain persons are systematically kept aside from extraction sites or places where clay is stored and processed: men when the craft is in the hands of women, women in opposite situations, uninitiated people, members of distinct social groups from the potters, little girls or boys, pregnant women, menstruating women, twins, warriors, etc. Likewise, artisans must avoid doing particular things on the eve of extraction or when engaging in clay collection: having sexual intercourse, talking, singing, swearing, urinating, manipulating certain objects, eating particular food, etc. Rituals and sacrifices (e.g., prayers, food offerings) may also be performed at the extraction site.

Clay Processing

As in most places around the world, African potters never use clays in their raw state. Processing operations may be grouped into four main categories: pretreatment, removal of nonplastics, addition of nonplastics, and homogenization.

Pretreatments usually consist in leaving the raw materials to dry, soak, or sour for hours, days, weeks, or even months. Soaking is usually done in a pit, an old jar, or a plastic container and used when clay is extracted in a dry state. It aims at allowing the material to regain its plasticity. If clay is already wet, the aim may be to obtain a better workability through increasing the amount and distribution of water between particles and pores. A long soaking time may also help in increasing plasticity through pH alteration and the subsequent flocculation of clay particles, but such souring process is quite rare among African potters.

When clay is sufficiently dry or wet, undesirable nonplastics may be removed through a series of techniques. The most common one is hand sorting, as potters usually remove coarse

impurities such as pebbles, roots, or leaves when manipulating clay. But there are several other ways of controlling clay composition and texture. For example, potters may pound the clay on a stone or in a wooden mortar or grind it with lower and upper grinding stones. Finally, nonplastics may be removed by sieving with baskets, pierced calabashes, or imported nylon meshes. Potters may also remove the coarser fraction of nonplastics by shaking the crushed raw materials in a calabash or by winnowing it with a winnowing basket or a calabash. A last technique, levigation, is quite rare in Africa. Here, the material is mixed with water until reaching a colloidal state. After having removed the larger, heavier particles on the bottom of the container, water is left to evaporate and the finer fraction is retrieved (David, 1983; Gally & Sauvain-Dugerdil, 1981).

Generally called “tempering,” the addition of plastic or nonplastic elements to the clay matrix involves a large variety of materials: other clays, dust, mud, termite heap clay, sand, gravel, rocks (calcareous rocks, gneiss, schist, and asbestos), iron stone, grog (crushed, grounded, and/or sieved potsherds; Fig. 1 – by far the most common material), fired earth, ash, straw, cereal husks, grass, stems, bark, dung (horse, cow, goat, or donkey), shells, calcareous solution (grounded and sieved calcareous rock mixed with a large amount of water; Sall, 2005), or bark decoction.

The last processing step usually consists in a thorough homogenization of the material. Such operation is mandatory in clay processing and has a determinant impact on clay workability. It may be done in different ways: kneading with the hands, trampling with the foot, or pounding with various kinds of tools and supports (the most common ones are mortars and pestles, lower and upper grinding stones, and handles of diverse farming tools). Due to the frequent combinations of the four categories of treatments, as well as the diversity of tools, gestures, and materials involved, there exist hundreds of technical variants across the African continent. Such diversity sometimes leads processing techniques to become cultural markers at local or regional

Ceramics in Africa,

Fig. 1 Pounding sherds in wooden mortars for obtaining grog, the most common temper in Africa. Note the use of tools and postures identical to those used in food processing

scales (Corniquet, 2011; Gosselain, 2008; Livingstone Smith, 2000).

Potters often explain that they act the way they do because of tradition (i.e., because of the way they have been trained), but also because using other processing recipes would lead vessels to break during drying, firing, or utilization. Such a conception may justify the use of different processing techniques in relation to the intended function of vessels or vessel parts. Among Koma-Gimbe of Cameroon, for example, potters simply pound the clay when making small vessels but add sand when making large beer brewing jars. They explain that jars would crack when drying if they did not do so (Livingstone Smith, 2000). Others examples of the use of different processing recipes for different uses have also been collected in other areas (Gallay & Sauvain-Dugerdil, 1981; Herbich & Dietler, 1991; Nicholson, 1929; Tobert, 1984; Trowell, 1941). Most commonly, however, potters use a single processing technique, irrespectively of the intended function of the vessels.

Another factor that explains the use of specific processing techniques is the relationship with techniques used in other realms of activity, such as food processing and agriculture. For instance, staple foods and clay may be prepared with similar tools and gestures and according to similar recipes. In the Bariba village of Tourou (Benin), for example, potters pound the clay in a wooden

mortar and separate the fine and coarse fraction by shaking the material in a calabash. Then, they pound the coarse fraction a second time, and let it soak in a jar placed in the sun. When the liquid is sufficiently thick, it is sieved through a pierced tin can and mixed with the fine fraction of the raw material. Potters explain that this mixture acts as cement and that the best millet porridge is obtained in a similar way. Similarly, the clay desalinization technique observed among certain Jola Kasa potters of Casamance echoes agricultural practices in mangrove zones (Sall, 2005).

Symbolic or religious concerns may also influence clay-processing strategies (see examples in Gosselain, 1999). For instance, some Boko potters of Benin take great care in extracting all rootlets from the raw material. This is because rootlets are used to prepare a medication that prevents potters from “swelling” when fashioning vessels. Some West African potters often recycle archaeological sherds into grog, as they consider this material to possess particular qualities because “ancestors knew how to make stronger pots” or because “what has lain underground is stronger than what lies on the ground” (Livingstone Smith, 2007). Another example comes from Tukolor potters of Senegal who stop adding dung to the clay when they settle in Soninke communities, where dung is considered impure (Gelbert, 2001).

Ceramics in Africa,

Fig. 2 Shaping a vessel with the diverging pounding technique, on a concave wooden anvil, with a clay tamper (Photo by Olivier Gosselain)

Shaping

In most instances, the shaping process must be separated into two specific operations, according both to their purpose and the set of tools and gestures involved: (1) roughing out and (2) preforming. During roughing out, potters transform a lump of clay and/or joint pieces of clay together in order to constitute a hollow volume – the rough shape – whose form, often cylindrical, is not that of the finished product. During preforming, potters give the hollow volume its final geometric characteristics through scraping and smoothing operations.

Wheel throwing – not considered here – is only documented in North Africa, where male potters have used it for centuries. South of the Sahara, only passing references are made to the use of wheel throwing by a few male potters in the Lower Congo area. The Portuguese could have introduced the technique in the late seventeenth century (Vincentelli, 2003, p. 44), yet due to a lack of ethnographical information, it is impossible to know whether it is still used as such by Kongo potters.

Roughing Out

Techniques used in sub-Saharan Africa belong to seven main categories: (1) pounding in a concave form, (2) drawing of a ring-shaped lump, (3) superimposing and drawing of large rings, (4) molding (on concave or convex molds), (5) pinching, (6) drawing of a lump, and (7) coiling. As the last three techniques are

widely documented outside Africa, only the first three will be considered here.

The pounding technique – also called “tamper and concave anvil technique” – consists in placing a lump or a pancake of clay on a mat-covered depression or a concave anvil (wood, clay, or stone) and pounding it with the fist, a wooden pestle, or, more generally, a stone or clay tamper (Fig. 2). Progressing with rhythmic beating, the potter rapidly obtains a concave form that he/she turns continuously on the anvil or the depression while shaping it. This technique is used throughout the Sahel, from Mali to Egypt (Drost, 1967; Gosselain, 2001; Huysecom, 1992; Sterner & David, 2003). Two main variants have been identified so far, whose spatial distribution across the continent could correspond to distinct historical processes (Gosselain, 2010): (1) *converging pounding*, in which potters pound the clay from the edge of the lump toward its center, and (2) *diverging pounding*, in which they progress from the center toward the edge. In the drawing of a ring-shaped lump, the potter fashions a ring of 20–60 cm in diameter with one or several slab(s) of clay and pulls its wall up with the help of the fingers (Krause, 1985; Lawton, 1967; Livingstone Smith, 2007; Roy, 1989). In most cases, the lower part of the vessel is fashioned later with coils or a pancake of clay, after the upper part has been preformed and is sufficiently dry to be upturned. A variant observed in western Cameroon consists in fashioning the bottom part before the upper one (Nyst, 1996).

The superimposing and drawing of large rings is similar to the previous technique, except that the initial volume is obtained by superposing a series of crown-shaped rings of clay which are then carefully joined. So far, the technique has only been recorded in the southeastern part of Central Africa (Lorenz & Plesner, 1989; de Maret & Bulckens, 1978; Livingstone Smith, 2010; Woods, 1984).

The seven techniques mentioned above are seldom used as such by African potters. The shaping of medium to large vessels usually involves the combination of the last two of these techniques, with the consequence that a detailed comparison of actual shaping processes allows one to identify more than 50 variants across the continent.

In comparison with clay extraction and processing, the most striking aspect about the roughing out process is that it mainly relies on hand gestures. While techniques such as molding and pounding require specific tools and devices, it is especially the artisan's hands and fingers that act during the major part of the shaping process. Gestures associated with the roughing out process also stand apart because of their relatively specialized character. Few relations exist with other activities at this level and only body postures (e.g., working while bending over the rough out or sitting on the ground with legs wide apart) may find an echo in other domains than pottery making.

The reliance on specialized gestures has been identified as a crucial factor for explaining the frequent stability of shaping technique through time and space, as well as the possible coincidence between techniques and major social boundaries such as language, socio-professional groupings, or political units (Fowler, 2008; Gosselain, 2000, 2002). Their mastery involves a close interaction between two individuals and a training period that may span over several years, so that motor habits would be more resistant to change than other stages of the manufacturing process. Recent studies have showed, however, that borrowing processes may also affect the shaping stage (Gelbert, 2001; Gosselain, 2008; Sterner & David, 2003).

Another explanation could be that since potters frequently view shaping techniques as an inheritance and an index of their social affiliation, they develop a conservative attitude in regard to the transmission of technical practice at this level of the manufacturing process. This is the case among female potters of the Songhay blacksmith group in Niger, who have acquired the molding technique from their Bella neighbors (considered as former slaves) but have chosen to pass on their own pounding technique ("the true Songhay technique") to their daughters.

Preforming

Carried out in continuation of the roughing out operations, this stage aims at giving the vessel its desired shape. To this end, potters scrape and smooth the wall with a series of tools, exercising gradual pressures in order to deform the clay material.

To round off the body and make it bulge, potters scrape the outside and inside walls while supporting the wall with the other hand. The tools used for scraping the inside surface have a rounded or spherical form: rounded off pottery sherds, pieces of calabash, pods, large seeds, nuts, shells, or spoons. Moved horizontally or obliquely, they do not generate much displacement of clay since internal scraping aims essentially at modifying the shape of the body. Outside scraping and smoothing operations, on the other hand, allow the potter to mask irregularities and to heighten the vessel through the displacement of a rather large amount of clay. Such operations are typically carried with flat and oblong tools, such as flat sticks, spatulas, bones, blades, pods, shells, or corncobs.

Forming the neck may be achieved with different techniques, either in continuation of preforming the body or after having added one or several coil(s). A first technique consists in bending the upper part of the wall through horizontal smoothing of the inside wall. In this case, the potter exercises an increasing pressure on the smoothing tool, while supporting the wall with the other hand, until the appropriate shape is obtained. Another technique consists in smoothing the outside wall of the vessel horizontally

Ceramics in Africa,

Fig. 3 Forming the neck and the lip of a vessel with the fingers. A constant pressure is exerted on the wall while the vessel is rotated slowly with the other hand (Photo by Olivier Gosselain)

with a tool whose curvature corresponds to that of the neck. Rounded off sherds or calabash pieces are typically used to that aim. A last technique consists in pinching the rim between the fingers (directly or with the help of a leaf, a rag, or a piece of leather) and rotating the vessel slowly with the other hand while exerting a constant pressure on the rim and progressively tipping up the hand toward the exterior (Fig. 3).

Finally, some potters form the lip of the vessel through constant pressure between fingers – or with the help of any supple material – as in the neck-forming method described above. Depending on the position of fingers, the pressure exerted, and the materials used, lips may acquire a rounded or sharp profile or bear a groove. The rim may also be shaped through smoothing with a flat or slightly concave tool such as a spatula, a stick, a bone, or the nervure of a large leaf. Here also, the potter usually rotates the vessel while exerting a constant pressure on the tool or, alternatively, moves the tool itself on the rim. A last method consists in adding one or several coil(s) above the rim or on its side and smoothing it with fingers or a supple material.

The individual dimension of preforming operations must be stressed. While frequently sharing a pottery tradition with a larger group of people, individual potters often develop idiosyncrasies at this level of the manufacturing process, through the specific ordering of operations and the way tools or fingers are used (Kaneko, 2007). Minute variations in profiles – neck, lip, handle, or

base – are also likened to “signatures,” which can be recognized as readily by eye as by touch (Gosselain, 2002, pp. 113, 115).

Another striking characteristic of the preforming stage is its permeability to innovation. Starting from simple and common forms, artisans are able to innovate in order to meet new demands (e.g., flowerpots, moneyboxes, stills, or incense holders) or to modernize the aspect of their products (Argenti, 1999). This explains the current appearance of a new generation of flat-bottomed pots fitted with handles, which are faithful copies of the aluminum pans produced in urban environments. The production of such vessels may also allow individuals to position themselves as experts and agents of modernity within their community.

Decoration

Decoration occurs either after shaping, while the paste is still wet, or after drying or even firing. In the first case, the techniques used belong to four large categories: (1) grooving, (2) incising, (3) impressing, and (4) appliqué.

Grooving consists in tracing lines or figures on the surface of the vessel with the fingers or a tool with a rounded or sharp extremity: sticks, stalks, thorns, ends of calabash scrapers, sharp stones, bones, shells, nails, bicycle spokes, bracelets (drawn on the surface), bundles of stalks or thorns held between finger or driven into a clay ball (Fig. 4), hair combs, and indented pieces of calabash.

Ceramics in Africa,

Fig. 4 Decorating a vessel with a comb-like device
(Photo by Olivier Gosselain)

Incising is similar to grooving, except that the tools used have a sharp cutting edge so that clay surfaces are actually incised. Such tools include knives, spearheads, or scraps of metal.

Impressing is done with distinct tools and methods. The simplest is to press any kind of device or material (fingers, natural objects, sticks, combs, or carefully designed wooden or iron stamps, as those used in the Inland Niger Delta; Gallay, Huysecom, & Mayor, 1998), in order to make a single impression that may be subsequently repeated on the surface. Another method consists of pressing and rocking convex devices such as blades or indented combs and bracelets on the surface and obtaining zigzag-like rows of impressions. Rouletting is a third technique, in which natural objects (corncobs, shells, fish vertebrae, plant parts) or roulettes (made by carving wood or twisting, knotting, braiding, coiling, or wrapping fibers) are rolled on the vessel's surface to obtain regular patterns (Haour et al., 2010).

Appliqué corresponds to any kind of clay elements added to the vessel surface, e.g., coils, buttons, spikes, and human or animal figures.

Decoration made on dry and hard surfaces comprises painting and specific surface treatments. The most usual ones consist of applying a slip made of iron-rich clays, crushed beforehand on a stone or in a mortar, and subsequently sieved and diluted in water. The application is made with the hand or a rag. In many instances, slipped surfaces are then carefully polished with

round stones or strings of seeds (mostly from baobabs) or cowries. The resulting effect, after firing, is a dark-red and shiny surface. Polishing may also be done on unslipped surfaces or with graphite, as among several South African populations (Bell & Calder, 1998; Fowler, 2008; Lawton, 1967).

Painting occurs either before or after firing. In the first case, by far the most common, it is done with various mineral pigments diluted in water and occasionally mixed with gum arabic, salt, or sugar, all elements that are said to favor adherence on vessel walls. Pigments are applied with a feather, a millet ear, a stalk, or a stick with a crushed or rag-wrapped end. In southwestern Niger, Bella and Zarma potters use a blade for drawing thin lines and motifs (Fig. 5). Postfiring painting is essentially observed in South Africa or in modern contexts, where vessels are aimed at tourist or city markets. Potters then use industrial paints and inks.

Regardless of the techniques, tools, or materials, a striking feature of decoration is the casual way in which most potters talk about it. Decoration would essentially be a matter of "simple embellishment," "like a hairstyle or clothes," the main function of which is to "attract the customer's eye." In some cases, even the aesthetic function of decoration is questioned, as when potters explain that roulette impressions are simply a matter of modifying wall texture to prevent pots from slipping when manipulated (Bredwa-Mensah, 1996; Priddy, 1971).

Ceramics in Africa,

Fig. 5 Applying a mineral paint with the help of a blade (Photo by Olivier Gosselain)

C

This does not mean that artisans proceed randomly, outside rules, or reference frameworks. On the one hand, pottery decoration is but an ornamental manifestation among others in a given context. Aesthetic choices may be influenced or even channeled by practices unrelated to pottery making. For example, there exist numerous parallels between vessel ornamentation and tattooing or scarification (Barley, 1994; David, Sterner, & Gavua, 1988; Ritz, 1989), as well as architecture or other elements of material culture (baskets, gourds, aluminum pots). On the other hand, if decoration is obviously open to innovation (e.g., the current vogue of painted inscriptions in West Africa), change mostly affects the components of the decors, rather than their organization or “grammars.” Interestingly, the latter could be related to the symbolic function of decoration or the expression of collective identities (David et al., 1988).

Drying

There exists a broad palette of practices and attitudes in regard to drying. Some potters deem it necessary to place the wares in the sun during the early stage of drying, while others take great care to shelter them during the first hours, the first days, or even the whole drying process. Similarly, some may wait several weeks or several months before firing the vessels, while others do it after 2 or 3 days. While drying periods are often shorter in dry areas than in tropical areas,

variations seem essentially related to personal conceptions and schedules, rather than climatic variations or the chemical and physical characteristics of raw materials. Thus, potters who make vessels on demand or frequent weekly markets generally resort to short drying periods. If necessary, wares cracked from too fast a drying are simply repaired with fresh clay.

Such flexibility in drying procedures is due, in part, to the accommodating nature of the raw materials used in Africa. But it may be reinforced through the use of preheating techniques that allow the gradual evaporation of residual water. For instance, pots may be placed around or above a cooking earth (Gosselain, 2002, pp. 145–146; Priddy, 1971; Woods, 1984), on glowing embers (Kanimba & Bellomo, 1990; Mercader, García-Hera, & Gonzalez-Alvarez, 2000), or on a rack-like structure below which a fire is kept going, as among several Kongo groups from Central Africa (de Maret, 1974; Mpika, 1986).

Firing

Although the emphasis will be put here on fuels and structures, several other aspects of firing may be taken into consideration, including the scheduling of firing events, the location of firing structures, the way vessels and fuel are positioned within the structure, the overall firing schedule (duration, refueling, way of assessing the degree of firing of the wares), or the identity of people taking part in the operation.

Ceramics in Africa,

Fig. 6 Firing structures used in Africa: (1) bonfire, (2) elevated bonfire, (3) bonfire with isolation, (4) depression, (5) pit, (6) pit with isolation, (7) oven, and (8) updraft kiln (Drawing by Yvette Paquay)

Fuel

As summarized by Livingstone Smith (2001, p. 993), almost all categories of combustible materials are used for firing pottery in Africa, from sawdust to rubber tires. Used independently or combined in various proportions, they may be grouped into three main categories, corresponding roughly to those made by the artisans themselves when asked about their conception of “appropriate” and “inappropriate” fuels: (1) manure of cows, donkeys, camels, or horses; (2) light materials (dry grass or cereal stalks, cereal chaff, palm fronds, leaves, twigs, barks, or roots); and (3) heavy materials (branches and logs from dozens of tree species).

Neither the firing structure nor the firing conditions possibly sought by potters seem to impose restrictions on the selection of fuel materials. With the notable exception of manure, whose combustion is slower, all the fuels used throughout Africa allow potters to obtain similar firing schedules and temperatures.

Structure

Eight firing structures are documented in Africa (see details in Drost, 1967; Gosselain, 2002, pp. 153–162): (1) bonfire, (2) elevated bonfire, (3) bonfire with isolation, (4) depression, (5) pit, (6) pit with isolation, (7) oven, and (8) updraft kiln (Fig. 6).

Bonfires are the most commonly used structures in Africa. Pots are placed on a bed of fuel, at ground level, and covered with another layer of fuel. Such structures vary tremendously in size (50–250 cm in height and 50–700 cm in diameter), firing duration (from 20 min to several hours), as well as the number of vessels fired at once (from 1 to 500). The number pieces may depend on the stock available at the time of firing but also personal conceptions. For example, some Gbaya potters from Cameroon deem it impossible to fire more than one to three vessels at once. They thus multiply firing sessions or construct several bonfires side by side.

So far, elevated bonfires have only been observed in the Great Lakes region, among the Twa of Burundi and Rwanda and the Konjo of Uganda (Célis & Nzikobanyanka, 1984). The technique consists in placing vessels on elevated rack-like layers of branches placed on four or five big stones and covering them with fuel. During firing, they fall gently on the ground as the branches gradually burn down.

Bonfires with isolation differ from simple bonfires in that a layer of fireproof materials – sherds, enamel wares, sheets metal – is placed either between the vessels and the upper layer of fuel or upon the whole structure. In the first case, the aim is to avoid color variations caused by contacts between fuel and vessel surfaces. In the second, the aim is to shelter the structure from the wind.

Depressions are shallow structures dug in the ground (between 20 and 40 cm depth) in which vessels stand partly above the ground when having been placed on the fuel bed. Their shape is circular, oval, or rectangular, with diameters (or sides) ranging from 100 to 500 cm. As for bonfires, important variations are observed in the number of wares fired at once and the duration of the firing. Variations also exist in the way vessels are positioned within the structure. For instance, while most potters place them horizontally or vertically, some place them upside down on the bed of fuel, in order to obtain a dark and shiny internal surface, as among the Zaghawa of Sudan (Tobert, 1984) or Hausa and Kanuri of Niger.

What differentiates pits from depressions is that, in the former structure, vessels remain below the ground surface after having been placed on the fuel bed. Their depth always exceeds 50 cm and may reach as much as 100–150 cm, for a diameter ranging from 50 to 400 cm. Another difference pertains to the duration of the firing, which is often several hours long. In a variant observed among Bamileke Fe'fe' from western Cameroon (Gosselain, 2002) and Kongo Manyanga from Congo (Mpika, 1986), the wares are placed on a rack-like wooden structure standing above the pit and gently tipped in the hole in the course of firing.

Pits with isolation resemble bonfires with isolation in that a layer of fireproof materials is placed either on the vessels or on the upper layer of fuel. This technique is commonly used in southern Africa (Krause, 1985; Lawton, 1967) and throughout the Sahel area, from Senegal to Sudan. Here, the firing usually lasts a whole night, even though the fire actually burns for a few hours.

Ovens are wall-enclosed structures within which vessels are not separated from the fuel. Such structures have only been documented in West Africa. They are made of mud, with a height of 50–180 cm and a diameter of 100–400 cm. The base of the wall has one or several hole(s), through which fuel (usually stalks or grasses) is charged during firing. 20–200 vessels may be fired at once in such structure. They are piled and subsequently covered with fuel and/or a layer of sherds. A simpler oven technique, observed among some Yoruba of Nigeria (Fatunsin, 1992, pp. 39–40) and Bariba of Benin, consists of firing vessels in a bottomless jar placed on mud bricks upon a small fire. Such technique is only used for small pieces.

Updraft kilns are particularly rare in sub-Saharan Africa. So far, they only have been observed in western Nigeria, among the Nupe of Bida (Nicholson, 1934; Vernon-Jackson, 1960) and the Yoruba of Abeokuta (Fatunsin, 1992). While such firing structure is constituted of a circular mud wall – as ovens – fuel is placed in a distinct chamber and separated from the

vessel with sherds or a perforated clay plate. They are in fact strongly reminiscent of the fish dryers used along the River Niger, within and to the north of the Nupe area.

Measurements made in the field show a considerable homogeneity in firing conditions, despite the variety of fuels and structure used throughout the continent. Whether in regard to temperature rise, maximum temperatures, or the time of exposure to specific temperature thresholds, each technique allows for similar results (Livingstone Smith, 2001). Such homogeneity echoes the way in which potters determine the completion of the firing process: in most instances, they retrieve the vessels or stop refueling when vessels' walls become incandescent.

There exist multiple relationships between firing techniques and techniques used in the realm of food processing (Gosselain, 2002, p. 165). But not with metallurgy, even in societies where male blacksmiths and female potters belong to the same endogamous subgroup. The fact that both activities are respectively practiced by different genders and in different circumstances would seem to hamper technical transfer. As other stages of the manufacturing process, firing is also surrounded by a series of prescriptions and prohibitions. Yet, they are both less numerous and less influential in technical terms, as they aim essentially at avoiding "evil" or "impure" individuals.

This worry stems from the public and collective character of the firing process. In many regions of Africa, artisans associate with relatives, friends, or neighbors for firing their wares. Such associations do not only help in alleviating their work but also meeting scheduling constraints (e.g., the existence of weekly markets) when only a few firing locations are available. Interestingly, communal firings often give rise to micro potting communities when artisans start to regroup on a regular basis. Operating within broader communities, they are characterized by the existence of close social bonds between members and the development of specific technical practices not necessarily limited to the firing process (Corniquet, 2011).

Postfiring

In many regions of Africa, vessels are subjected to various treatments after firing, either when retrieved red hot from the fire or after having cooled off. Aiming at improving the physical characteristics and/or appearance of vessels, postfiring treatments may be grouped into five categories: (1) organic coating, (2) resin application, (3) smearing, (4) smoking, and (5) water sprinkling or soaking.

Organic coating is by far the most common treatment. It consists of coating the surface with an organic mixture made from parts (bark, fruits, leaves, branches, roots) of several dozen tree species, the most common of which are *Bridelia ferruginea*, *Bridelia micrantha*, *Parkia biglobosa*, *Parkia filicoidea*, *Diospyros mespiliformis*, *Ximenia americana*, *Pterocarpus angolensis*, and several *Acacia* and *Syzygium* subspecies (see details in Drost, 1967, pp. 174–182; Gosselain, 2002, pp. 184–190). After having been crushed, the material is boiled in water (decoction), put into hot water (infusion), or soaked at ambient temperature (maceration). Application is done by immersing hot vessels in the mixture, sprinkling it on the walls, or smearing the surface with the help of a series of brushlike tools. Alternatively, cooled off vessels are coated with the help of a rag. Besides having a decorative purpose, organic coatings are said to have strengthening and waterproofing effects.

Resin application is solely aimed at waterproofing the vessels. In this case, the inside surface is coated with resin extracted from several tree species – e.g., *Canarium schweinfurthii*, *Copaifera demeusei* or *mildbraedii*, various *Acacia* species, *Euphorbia candelabrum*, *Dodonea viscosa*, and *Guizotia abyssinica* – either by melting it directly in the vessel or pouring it in after melting. The vessel is then rotated rapidly for ensuring a homogeneous surface coating.

Organic materials may also be smeared on the surface or cooked in the vessel in order to strengthen or waterproofing them: leaves of *Ricinus communis* or *Sida rhombifolia*, oil or sap from *Raphia vinifera* or *Elaeis guineensis*, fruits, fibers, roots, cereal husks, milk, porridge,

or cow dung (see examples and details in Gosselain, 2002, pp. 191–192).

Smoking aims at covering the vessel surface with wood tar in order to give it a black shiny aspect – and according to several potters, improving their strength and waterproofing. To that aim, vessels retrieved red hot from the fire are usually buried in organic materials such as grass, cereal husk or chaff, animal manure, fruit pods, and bark or wood shavings (see examples in Gosselain, 2002, pp. 192–193). Another technique, observed in the Great Lakes region and South Africa, consists in maintaining vessels above a small fire (Armstrong, Whitelaw, & Reusch, 2008; Fowler, 2008; Trowell, 1941).

Lastly, vessels may be immersed in, or sprinkled with, freshwater or boiling water (see examples in Gosselain, 2002, p. 193). Here again, the aim is to waterproof and strengthen the wares.

As with clay processing or firing, artisans often emit strong views about the choice of ingredients, preparation recipes, or application techniques. As diverse – and even antagonistic – as they are, they seem to follow similar logics. For instance, sub-Saharan potters use at least 50 different plant species for making organic coatings, but few of them know about the existence of other plants than the ones they use, and most believe that there is simply no alternative to their choice. The same applies to the preparation of the plant parts or the application technique. Seen from a comparative and analytical perspective, however, all choices are perfectly justified from a technical or aesthetical point of view. The chromatographic analysis of various fruits and barks used in sub-Saharan Africa indeed reveals the presence of a specific category of tannins, the procyanidins, with excellent coloring and waterproofing properties (Dialo, Vanhaelen, & Gosselain, 1995).

The most striking aspect of the postfiring stage is its connection with many other domains of activity. For example, most of the plant species exploited by potters are also used as food, dyes, basketry materials, waterproofing materials for wall and pavements, and, above all, pharmacopoeia. This last domain reveals interesting ties, as the illnesses and injuries treated with the help of

preparations similar to those used by potters are mostly characterized by discharges (Gosselain, 1999, 2002, pp. 197–198, pp. 210–211): wounds, diarrhea, gonorrhea, hemorrhage, menorrhagia, ulcers, etc. Pots are thus treated as human bodies, and reversely. Similarly, postfiring treatments are often connected to birth and circumcision rites. What is at work, here, is the materialization of an extremely widespread association between pottery making and human beings (Armstrong et al., 2008; Barley, 1994; David et al., 1988; Gosselain, 1999; Ritz, 1989) that seems to channel potters' behavior in relation to the choice of ingredients as well as processing and application techniques.

This fact illustrates perfectly why a *chaîne opératoire* cannot be reduced to mere actions on matter. As stressed by Lemonier (1991) and many other scholars, techniques do not solely aim at transforming materials or acting upon the material world. They also respond to a series of social, political, economical, and symbolic concerns, whose echo may be found at any level of the manufacturing process as we have seen throughout this article.

Ceramics in Burma

Myo Thant Tyn

Kyeemyindine Township, Yangon Region,
Myanmar Ceramic Society (MCS), Yangon,
Yangon Region, Burma (Myanmar)

Prehistoric Earthen Wares

Late Palaeolithic Age: The prehistoric tradition of Myanmar (Burma) earthenware could be traced back as far as $13,400 \pm 200$ years before the present (BP) with some simple cord-marked potsherds, an earliest Hoabinhian culture or earlier than the Spirit Cave (Thailand), from the excavation of Padah-Lin caves in the Ywa-ngan Township (Shan State) in January 1969. The late Anyathian (12000–6000 BP) culture site in Myanmar belongs to the late Palaeolithic Age (75000–9500 BP).

Neolithic Age: The corded earthenware culture of the Neolithic Age (6000–4000 BP) was discovered at various places within the great basin where the Chindwin and Ayeyawady rivers flow from Kani down to Letpanchebaw and Thegone. Red-painted pottery from Halin and Twintaung are also included in this culture.

Other prehistoric earthen pottery has been found, mostly by excavation, in Taungthaman (late Neolithic) (Fig. 1), and Nyaunggan (1500–300 BC) (Fig. 2).

Forming Technique: Much of the pottery recovered was plain and undecorated, being formed by coiling and paddling (without wheel) fine-grained clay tempered with sand which had turned a buff colour on firing. The turning wheel was supposed to be invented from about 5000 BP and found in continued use in about 950 BC (excavated finding at Nyaunggan). Forms comprise a variety of bowls with inverted, everted, and perforated rims and rounded, ringed, and tripod bases. A few have perforated lugs on the body while others are set on flaring foot-rims.

Uses: Such bowls probably served as oil lamps and receptacles for food, water and flour for both domestic and ritual purposes. In Nyaunggan, Bronze Age artifacts, including earthenware pottery has been excavated; among these some interesting sets of pots that might possibly have been used for distillation for alcohol or fragrance were found (Fig. 3). Consequently, small cylindrical pots something like beer cans were also found in an excavated site at Samon Valley (Bronze-Iron Transition Age) could be regarded as a distillate container for generating evaporated cooling effect. Ceramic earthenware in various forms also played a very important part in the lives of Myanmar people. From the late Palaeolithic period to historic times earthenware had been used for storing and cooking food, for ceremonial and religious purposes, and also for building and decorating houses, palaces, shrines and city walls. From birth to death, earthenware had a significant role in Myanmar. In many cases in ancient times, earthenware was buried in the grave so as to accompany the dead to other existences.

Decoration/Design: Although simple cord-marks are possibly the earliest design decorated on pottery surfaces since late Anyathian culture in Myanmar, better techniques and varieties of decoration or design seemed to appear in about 9000 BP. The technique for decorating earthenware changed and diversified in Myanmar since that time and falls mainly into two groups, incised

Ceramics in Burma,

Fig. 1 Neolithic earthenware from the west bank of Lake Taungthaman (Amarapura) (Than Tun "Pottery in Burma, 1972")

and impressed. The incised technique used a sharp or pointed tool, a comb or a shell to cut or punctuate the required pattern on the clay surface. In the impressed technique, the pattern was impressed into the surface of clay rather than cut or appliquéd. The incised technique was normally used for lines and curving patterns whereas the impressed technique was used for the rest. Different tools and different methods were used in the impressed technique. A paddle wrapped with cord, basket, net or fabric was used to make impressions on the clay surface and such products are called cord-marked, basket-marked, net-marked or fabric-marked pottery. The other type of paddle impressed method was carved-paddle-impressed where patterns were carved on the surface of the paddle and made impressions on clay surface layer by beating with the

paddle. The other one was the stamped-impressed method where the stamp with pattern was pressed onto the clay surface. The roulette method was another impressed technique where a roller with patterns (called roulette) was pressed and rolled on the clay surface.

Protohistoric and Transition Period Earthenware

Analysis Through Design: Comprehensive study of design from the assemblage of 3,000 potshards from Taungthaman, Beikthano, Halin, Tagaung, Bago, Mrauk-U, Amarapura and Twante reported by various scholars was conducted. Although these designs look simple enough as individuals, when studied collectively in large numbers some

Ceramics in Burma, Fig. 2 Earthenware excavated from Nyaunggan in association with burials containing bronze weapons (Ni Ni Myint, 1998; Sein, 2003)

cultural link can be deduced for a better understanding of the prehistoric and protohistoric culture of Myanmar.

Neem-Leaf Design: Analysis of the Neem-leaf design is an example for deduction. Through close analysis referring to the above technique the design could be classified into two categories, geometric and zoomorphic decorations. In the geometric group carved-paddle-impressed Neem-leaf design was used the most (about 50 %). Out of Neem-leaf pattern shards the majority was collected from Delta (Tawnte and Bago) (Fig. 4). Only a few were observed in

upper Myanmar. This was also found to be a missing link for the migration of carved-paddle-impressed (Neem-leaf pattern) pottery tradition into island Southeast Asia proposed by the eminent scholar Dr. Solheim II. He said that, “the movement of carved-paddle-impressed tradition was towards the east from India by the way of Burma as early as 2000 years ago so it may have spread through the Malay maritime world from India or Burma”. Now it is clear that Twante could be the link in solving the migration problem of this tradition from India to island South-east Asia through via Myanmar. Moreover it

Ceramics in Burma,

Fig. 3 Earthenware distillation unit excavated from Nyaunggan

Earthen Distillery Unit

Earthen Beer Can

Plate 2

Plate 3

Try pod Lid in Detail

could also infer that Neem leaf type pottery tradition started in Twante as early as 2000 BP and then migrated to upper Myanmar.

Historic Earthenware and Glaze Ware: Pyu Period

The Pyu period is the transition from the prehistoric to the historic civilization of Myanmar; it flourished from about third Century BC to about ninth Century AD. During a millennium Pyu people were able to accomplish indigenous development of Pyu towns and cities such as Samon Valley (fifth Century BC-first Century AD), Beikthano (second Century BC-fifth Century AD)

(Fig. 5), Tagaung (earlier than first Century AD), Halin (second Century AD-ninth Century AD) (Fig. 6), Sriksetra (third Century AD to ninth Century AD) and Pinle (Mai-mau) (fifth Century AD) from small prehistoric villages in a way that was not previously possible in Southeast Asia. There were also numbers of self-regulating villages and towns of Pyu people outside the cities area. These Pyu people left an impressive record of their lives and deaths in the archaeological evidence.

Excavation of Pyu Cities: A series of excavations was conducted at important Pyu cities by the Archaeological Department at Beikthano (since 1958), Halin (since 1963) and Sriksetra (initially in 1907 and since 1963). They collected a considerable amount of information on ceramic

Ceramics in Burma, Fig. 4 Neem leaf (carved-paddle-impressed tradition) design on earthenware pottery shards from Twante

artifacts. As these artifacts are specifically related to the Pyu culture, they are being employed as an allegoric tool for tracking ancient Pyu. Earthen artifacts such as burial urns, bricks with marks/finger-scratches (Fig. 7), potter marks/Pyu-alphabet (Fig. 8), earthen and glass beads, earthen votive tablets and earthen seals obtained from the archaeological excavations are unique tools for identification.

Glazed Ceramics in Pyu Period: Although many earthenware objects emerged from excavations glazedware is still missing and has not shown up as archaeological evidence in any of these Pyu

sites. However evidence for the existence of glazed ceramics tradition in Pyu period is now in hand. The direct eyewitness is the Ngakywe-Nadaung pagoda (eighth to ninth Century AD) on which tin-lead glazed bricks were inlaid (Fig. 9). From logical deduction based on the evidence [potter marks of Pyu, seventh Century AD stone inscription mentioning Kalathapura (City of Pots) and fifth Century AD dated Buddha bronze image being covered with green glaze], a hypothesis was proposed that Pyu potters might have been the first to employ glazed ceramic technology (possibly low temperature

Ceramics in Burma, Fig. 5 Earthenware excavated from Beikthano (Vishnupura)

lead glaze) in Myanmar at about fifth Century AD or earlier.

Revelation of Glazed Ceramic History in Myanmar: The history of Myanmar glazed ceramics has just emerged from its obscured existence. Although there was a long tradition of Martaban jars most of the ceramic historians were less enthusiastic about including Myanmar into their study because of the scarcity of ancient production sites. This dormant period stretched along until 1984 when some mysterious green-and-white glazed wares popped up in the Tak and Omkai areas near the Thai-Myanmar border (Figs. 10 and 11). While beautiful green-and-

white ware was popular in antique markets the controversy of its origins triggered the enthusiasm of ceramic historians. Being passionate lovers of Asian ceramics, the Japanese brought large amounts of green-and-white wares back home and identified that their origin is Myanmar through lead isotope ratio analysis. These findings aroused the interest of ceramic historians in such a way that the Myanmar Glazed Ceramics tradition suddenly became quite important. Ceramic historians and local enthusiasts joined forces to reveal the ancient Myanmar glazed ceramic tradition so as to elucidate the ambiguity of green-and-white wares.

Ceramics in Burma, Fig. 6 Earthenware excavated from Halin

Ceramics in Burma, Fig. 7 Earthenware bricks with marks and finger-scratches

Due to this collective effort about a hundred production sites consisting of nearly 2,000 kilns were discovered in different places such as Lagumbyee (Yangon-Bago Regions); Pathein,

Old-Myaungmya and Ngaputaw (Ayeyawady Region); Twante (Yangon Region); Bagan and Inn-Wa (Mandalay Region); Honar (Shan State); and Mrauk-U (Rakhine State). Some

Ceramics in Burma,

Fig. 10 Tin-lead glazed white ware from Tak-Omki near Thai-Myanmar border

**Ceramics in Burma,**

Fig. 11 Green and white ware from Tak-Omki near Thai-Myanmar border

possible sites were identified in Martaban, Donzayit and Mawlamying (Mon State); Hmawbe and Hlègu (Yangon Region); Hinthada, Maubin and Bogalay (Ayeyawady Region); Pakhangyi (Magway Region); Chaung-U, Myin-hmwe, Panpin and Myin-mu (Sagaing Region); Keng Tung (Shan State); Vesali (Rakhine State); Tagung (Sagaing-Mandalay regions) where

many glazed shards, wasters and supports were found.

Out of these listed kilns few low temperature updraft kilns producing alkaline, lead and tin-lead glazewares are situated in Bago, Bagan, Inn-Wa and Myin-Mu along Ayeyarwady River banks in Central Myanmar. The rest are high temperature crossdraft (surface and inground)

kilns capable of producing lead or tin-lead glazeware and high temperature ash glaze (celadon) stoneware (Fig. 12).

Low Temperature Glaze Tradition: Lead or tin-lead glazeware was fired in an oxidized atmosphere at about 900–1100 °C in updraft kilns. It

Ceramics in Burma, Fig. 12 Celadon (ash glaze) of Myanmar 15th–16th AD

was generally accepted that low temperature updraft kilns originated in ancient Egypt where low temperature glazes (with lead as flux) were produced in early 4000 BC. The use of tin as an opacifier in lead glaze was also noticed in the Middle East (Persia) since 1100 BC when tin-lead glazed bricks marked with the name of the Assyria king, Tiglath-Pileser, had been found. Therefore it could be deduced that low temperature glaze tradition originated in the Middle East and spread. For East-bound migration, possibly both overland and sea routes of the Silk Roads might have reached Myanmar (Figs. 13 and 14). However since early 109 BC the overland Silk Road had been the conduit for envoys from West (Persia) that might penetrate from India into Myanmar by two routes: one linked to China and the other to Thailand (Dvāravatī), Cambodia (Funan) and Vietnam (Annam). Both routes involved Ayeyawady River which is navigable all the way down to its delta.

Since tin-lead glazewares are hardly known in China, the tin-lead glaze tradition of Myanmar possibly came directly from Persia through the inland Silk Road. The presence of turquoise (alkaline) and opaque (tin-lead) glaze-coated

Ceramics in Burma, Fig. 13 The overland silk road

Ceramics in Burma, Fig. 14 Trade routes among Pyu, China, India and SEA in ancient period (Dr. San Shwe, 2008)

bricks inlaid on the eighth to ninth Century AD dated Pyu-type Ngakywenadaung pagoda and excavated finds of turquoise, green, olive green and brown (alkaline, tin-lead) glaze shards from updraft kiln No.1 of Bagan etc. support the technological connection with Persia although the products were locally made. Based on the ancient Chinese chronicles and practical reasoning, Di Crocco postulated that Pyu city with green glaze brick wall mentioned by eighth Century AD Chinese chronicles was some ancient city in the Bagan area. Chronicles also mentioned Pyu people use tiles of lead and tin, silver coins and traded or battered in glazed jars. Bawzaing mine extracted silver as early as sixth Century AD with lead slag as a by-product containing at least 30 % lead and a bit of tin. Therefore a very large glazed ceramics industry must have existed around that period. Since some time is usually needed to attain such production level it is envisaged that

Pyu potters might have started their industry much earlier, say fifth or sixth century AD.

High Temperature Glaze Tradition: The high-fired stoneware glaze technology was discovered in the Shang-Yin period (1500–1027 BC) as having its origin in China. Wood ash or lime was employed as a flux in combination with silica and feldspar to produce celadon firing in reduced atmosphere at about 1250–1300 °C in crossdraft kilns. It is believed that celadon technology might possibly have come into Myanmar directly from China through East-Northern route although we do not know exactly when. However there is an indication for probable existence of a celadon manufacturing tradition in Myanmar (Bagan) at about eleventh to twelfth Century (Di Crocco, 1990). In recalling the fact that celadon stoneware from Myanmar (Twante) were being exported to Egypt as early as fifteenth Century AD the said indication is quite plausible.

As mentioned earlier there were signs of active updraft kilns in Central Mainland Myanmar at about sixth Century AD it is quite relevant to assume the indigenous evolution of the updraft kiln into the crossdraft kiln. However there is not enough evidence of transitional kilns in hand yet. Until then a provisional assumption of Chinese connection for crossdraft kilns has to be maintained.

While updraft kilns were mostly situated in the central mainland, crossdraft kilns were widely spread along the outward area of the country such as Rakhine State; Ayeyawady, Yangon and Bago Regions; Mon, Kayin and Shan States. Inground kilns were mostly concentrated in the West and West-Southern parts producing lead and tin-lead glaze wares whereas surface kilns in East and East-Southern parts producing ash glaze (celadon) wares. When and why the whole celadon production (except Honar, Shan State) was stopped and why lead glaze tradition was dominated until now are questions still to be answered.

Ceramics in China

Jiazhi Li, P. L. Leung, K. N. Yu and R. Wu

China was one of the earliest countries that possessed pottery, and was also the country that invented porcelain. She has a unique and sustained history of technique development of 10,000 years. The entire development can be summarized by five milestones and three technological breakthroughs. The outstanding achievements in this development constituted an indispensable contribution to Chinese culture (Table 1 and Map 1).

Five Milestones

The First Milestone: Appearance of Pottery in the Early Neolithic Age

According to archeological information, after the discovery of potteries of the Yangshao culture, the following were discovered:

Ceramics in China, Table 1 Chronology of ancient Chinese history

Neolithic period	6500–1700 BCE
Xia	2100–1600 BCE
Shang	1600–1100 BCE
Western Zhou	1100–771 BCE
Spring and autumn annals	770–476 BCE
Warring States	475–221 BCE
Qin	221–206 BCE
Han	206 BCE–AD 220
Three Kingdoms	220–280
Jin	265–420
Southern and northern	420–581
Sui	581–618
Tang	618–907
Five Dynasties and Ten Kingdoms	907–960
Sung	960–1279
Yuan	1279–1368
Ming dynasty	1368–1643
Hongwu	1368–1399
Jianwen	1399–1403
Yongle	1403–1424
Hongxi	1425–1426
Xuande	1426–1435
Zhentong	1436–1450
Jingtai	1450–1457
Tianshun	1457–1465
Chenghua	1465–1487
Hongzhi	1488–1505
Zhengde	1506–1521
Jiajing	1522–1566
Longqing	1567–1572
Wanli	1573–1619
Taichang	1620–1621
Tianqi	1621–1627
Chongzhen	1628–1643
Qing dynasty	1644–1911
Shunzi	1644–1661
Kangxi	1662–1722
Yongzheng	1723–1735
Qianlong	1736–1795
Jiaqing	1796–1820
Daoguang	1821–1850
Xianfeng	1851–1861
Tongzhi	1862–1874
Guangxu	1875–1908
Xuantong	1909–1911

Ceramics in China, Map 1 Map showing the kilns in different provinces in China (Adopted from Chen, 1990)

- Those of the Hemudu culture in Yuyao, Zhejiang Province about 7,000 years ago
- Those of the Cishan culture and the Peiligang culture about 8,000 years ago
- Those of the Pengtoushan culture in Li County, Hunan Province and the Jiahu culture in Wuyang County, Henan Province about 9,000 years ago
- Those at the Yuchanyan site in Dao County, Hunan Province, the Xianrendong site in

Wannian County, Jiangxi Province, and the Nanzhuangtou site in Xushui County, Hebei Province about 10,000 years ago

The raw materials for early pottery were all obtained locally. In particular, a common feature for the pottery of about 10,000 years ago is that they were all coarse sandy pottery with coarse and loose textures, so most of them were only small shards when unearthed, and only very few

Ceramics in China, Fig. 1 Microstructure (70×) of sandy pottery from the Nanzhaungtou site in Xushui County, Hebei Province

Ceramics in China, Fig. 2 Microstructure (350×) of sandy pottery from the Xianrendong site in Wannian County, Jiangxi Province

whole pieces could be restored. Their firing temperatures were about 700 °C. For examples, pottery from the Nanzhuangtou site in Xushui County contained big grains of hornblende and vermiculite (Fig. 1), and pottery from the Xianrendong site in Wannian County contained large grains of quartz, dickite, and muscovite (Fig. 2; Li, Xianqiu, Zequn, et al., 1996). This also explained why the pots from the Nanzhuangton site contained more calcium oxide (lime, CaO) and magnesium oxide

(MgO), and those from the Xianrendong site contained more silicon dioxide (SiO₂) and potassium oxide (K₂O). In this way, the amounts of calcium oxide and silicon dioxide can be used as characteristic constituents to differentiate between pots manufactured in the northern part and those manufactured in the southern part of China. The microstructure of the black pottery including charcoal from the Hemudu culture was rather peculiar (Li, Xianqiu, Zequn, et al., 1978) and is shown in Fig. 3.

Ceramics in China,

Fig. 3 Microstructure (165 $\times$) of black pottery including charcoal of the Hemudu culture in Yuyao, Zhejiang Province

Ceramics in China,

Fig. 4 Microstructure (140 $\times$) of an early proto-porcelain of Western Zhou dynasty from Jiang Shan, Zhejiang Province

The Second Milestone: Successful Firing of Stamped Hard Pottery in the Late Neolithic Age and Appearance of Proto-Porcelain in the Shang-Zhou Dynasty

It is generally accepted that stamped hard pottery first appeared in the late Neolithic age about 4,000 years ago (which could be regarded as the Xia period according to dating results) and that proto-porcelains first appeared in the Shang dynasty. Stamped hard pottery had lower contents of iron oxide (Fe_2O_3) than general potteries. The firing temperature was above 1,000 °C, and the maximum temperature could reach 1,200 °C. Proto-porcelains had even lower iron oxide content; they were in general below 3 %.

The highest firing temperature reached 1,280 °C. There were glaze layers of nonuniform thicknesses on the interior as well as the exterior surfaces of proto-porcelains. The glazed layer could be a green glaze with a grayish green or yellowish green color, or a yellow glaze with a greenish yellow or brownish yellow color. Generally speaking, the glaze was not tightly bonded to the body and could be easily delaminated. The glaze contains relatively high contents of calcium oxide, and is thus called *calcium glaze*. This kind of glaze is a unique high-temperature glaze created in China and is the earliest high-temperature glaze in the world (Fig. 4; Li, Xianqiu, Fukan, et al., 1985).

Ceramics in China,

Fig. 5 Microstructure (405×) of the glaze of a green-glazed porcelain from the Yue Kiln, Xiaoxiantan, Shangkyu, Zhejiang Province

The Third Milestone: Appearance of Green-Glazed Porcelain (Celadon) in Southern China in the Han-Jin Dynasty

The successful firing of the southern green-glaze porcelains, represented by the Yue wares in Zhejiang Province during the late East Han dynasty (AD 25–220), signified another leap in the development of ceramic technique in China. Porcelains first appeared in the world from this period.

Porcelain differed from pottery in that the porcelain appeared to be stronger and more compact. Most were white; some had a grayish tint. Their cross-sections had a glass-phase luster and the thin layer was slightly translucent. They had relatively high contents of silicon dioxide and aluminum oxide (Al_2O_3) and smaller amounts of fluxing agents; they could be fired at higher temperatures and had higher strength. The porosity as well as the water absorption rate was very small. As regards their microstructure, they contained relatively larger amounts of glass phase as well as a certain amount of Mullite crystals. The quartz remnants were small and rounded. The appearance, chemical composition, physical properties, and the microstructure described above are the characteristics of porcelain. Yingxing Song (a famous scientist in the Ming dynasty) describes them as having the “...appearance of white flesh and jade skeleton” in his publication *Tian Gong Kai Wu* (Exploitation of the Works of Nature).

The success of green-glaze porcelains in southern China was primarily attributed to the rich reserve of China stone in the southern part of China. Since at that time only China stone was used as the raw material for porcelain, this led to the early quartz-muscovite series of porcelains with high silicon and low aluminum contents in southern China. The success of green-glaze porcelains could also be attributed to the techniques derived from extensive experience in firing the stamped hard pottery as well as the proto-porcelains.

We use as an example the shard from a green-glazed stamped *Ci Lei* (porcelain drinking vessel) unearthed from the Yue Kiln in Xiaoxiantan, Shangkyu, Zhejiang Province. The iron oxide and the titanium dioxide (TiO_2) contents in its body and glaze are relatively lower, and the titanium dioxide content in the glaze is particularly low. The firing temperature reached 1,300 °C. The body contains relatively larger proportions of the glass-phase. The quartz remnants are small and uniform, while Mullite crystals are ubiquitous. The glaze layer contains extremely small amounts of bubbles and quartz remnants. The glaze layer is a rather thin transparent glass glaze. The anorthite crystallization layer is common at the body-glaze interface, which strengthened the bonding strength of the body and the glaze (Fig. 5). The water absorption rate of the body is only 0.28 %, and the bending strength is as high as 71 MPa. Its chemical

Ceramics in China,

Fig. 6 Kaolinite remnant in the body of a white-glazed porcelain of the Xing Kiln (350 $\times$)

composition, microstructure, and physical properties perfectly satisfy the requirements for contemporary porcelains (Li et al., 1978).

The Fourth Milestone: Breakthrough of White-Glazed Porcelain in Northern China in the Sui-Tang Dynasty

The breakthrough in white-glazed porcelain in northern China in the Sui-Tang dynasty (AD 589–907) was the result of the rich supplies of high-quality raw materials in northern China as well as experience over a long period of time. Its occurrence was another leap forward in porcelain techniques in China, and made China the first country to possess white-glazed porcelains (Li et al., 1985).

The techniques required by the white-glazed porcelains of Xing, Gong, and Ding Kilns are summarized below.

Use of New Materials and Improvements in the Recipes for the Body and Glaze

All the bodies of white-glazed porcelains of the Xing, Gong, and Ding Kilns made use of secondary settled clay with higher contents of kaolinite or kaolin clay, so their bodies contained more than 30 % of aluminum oxide. Figure 6 shows the microstructure of the body of a white-glazed porcelain of the Xing Kiln, in which a kaolinite remnant can be seen. Furthermore, feldspar was found in the recipes of the body of some white-glazed porcelains, and the potassium oxide content in these bodies could be above 5 %.

According to the silicon dioxide contents and α -quartz contents in the microstructure of the bodies, it can be inferred that the kaolin-quartz-feldspar porcelains emerged in the Sui and Tang periods in China. These were not found in the southern green-glazed porcelains. Even when kaolin clay started to be used for the Jingdezhen white-glazed porcelains during the late Song and early Yuan dynasties, these were only kaolin-quartz-muscovite porcelains. These two types of porcelain represented the two major white-glazed porcelain systems in northern and southern China. For some white-glazed porcelains of the Sui dynasty, the potassium oxide content far exceeds that of calcium oxide, the glaze of which is referred to as the alkali-calcium glaze. This is also never seen in the southern early green-glazed porcelains, and only starts to appear in the Jingdezhen sweet white-glazed porcelains during the Yongle period of the Ming dynasty and the Dehua white-glazed porcelains during the Qing dynasty.

Increase in the Firing Temperature and Improvement of the Kilns

The firing temperatures of white-glazed porcelains of the Xing, Gong, and Ding Kilns of the Tang dynasty reached 1,300 °C, and some reached as high as 1,380 °C. The increase of the firing temperature was certainly linked to the improvement of the kilns. The kilns used for the northern white-glazed porcelains in the Sui and Tang periods were up-draught Mantou kilns

Ceramics in China,**Fig. 7** Qichun relics of a Xing Kiln in the late Tang period

(Fig. 7). The improvements included big firing chambers, small kiln chambers, and double chimneys, which increased the drag force to enhance the firing temperature.

Use of Saggars and Improvement in Firing Techniques

The firing of Xing Kiln white-glazed porcelains during the late Sui and early Tang dynasties already made use of saggars (a sagger is a case made of fired clay in which porcelain and similar delicate items are enclosed while they are being fired in the kiln) for assembling and firing. The transition from open firing to firing in saggars was a breakthrough to enhance the quality of porcelains. This kiln was one of earliest ones which employed devices for firing in saggars, and possessed various saggars as well as various techniques according to the different forms of porcelains.

The Fifth Milestone: Time of Monochrome-Glazed, Polychrome-Painted, and Sculpted Porcelain from the Song to Qing Dynasty

All the famous porcelains from the Song dynasty to the Qing dynasty (AD 960–1911), such as the imperial wares, Ge wares, Jun wares, Ru wares,

Yaozhou wares, Linru wares, Cizhou wares, Jizhou wares, Longquan wares, Jian wares, Changsha wares, Qionglai wares, Dehua wares, Yixing wares, and the later Jingdezhen wares, were all world famous for their monochrome-glazed porcelains, polychrome-painted porcelains, and sculpted porcelains. These porcelains illustrated the great achievements in the sciences, techniques, and arts needed for Chinese porcelains.

Starting from the late East Han dynasty, the Zhejiang Province had been firing celadon with iron oxide as the colorant. Until the South Song dynasty, the black body celadons manufactured in its imperial kiln and the Longquan kiln were crystallization-phase separation-crackle-glaze porcelains. These porcelains made use of the microcrystals of Anorthite and the immiscible liquid droplet separated from the glaze to enhance the jade-like appearance, and exploited the different expansion coefficients of the body and the glaze to generate cracks with different patterns and to become a unique world famous decoration. On the other hand, the white-body celadons were manufactured in the Longquan kiln in large numbers and were

transported to different places in the world and have been collected by all major museums.

The celadons from the Ru Guan kiln and Linru kiln of Baofeng in Henan Province, as well as those of the Yaozhou kiln of Tongchuan in Shaanxi Province, also used iron oxide as the colorant. These porcelains also enjoyed a very good reputation in the world. The celadons from the Ru Guan kiln were particularly precious due to the short manufacturing periods and their small handed-down number.

Black-glazed porcelains emerged almost at the same time as the celadons. All the famous kilns in north and south China manufactured this kind of black-glazed porcelain from time to time, which used iron oxide as the main colorant. With the arrival of the Song dynasty, the techniques in manufacturing black-glazed porcelains had been significantly improved. The most unusual products included the hare's fur bowl of Jianyang, Fujian Province and the black-glazed bowl of Jizhou, Jiangxi Province. These developments were partially attributed to the habit of drinking tea at that time, and partially to the availability of the extremely complicated technology, which was unique in the world. The "hare's fur" was formed by crystallization and then phase separation (or direct phase separation), and then by recrystallization. Under different environments, products with different colors, such as the golden hare's fur and the silver hare's fur, can be formed (Chen, Shiping, Ruifu, et al., 1983a, 1983b). Among these, the fur streaks of some will display different colors in the optical spectrum, which can interchange with each other when observed from different angles. This product is called *Hao Se Bian Yi* bowl (hare's fur bowl with alterable colors), which is a product of the science and technology that integrated the phase separation and crystallization in physical chemistry and thin-film interference or diffraction grating in physical optics. The Hao Se Bian Yi cup transported to Japan was called the *Yohen Temmoku* and was considered a national treasure.

The glaze of the Jun kiln in Yu County, Henan Province was a new product. It was a red glaze colored by copper compounds, or a multicolor glaze with nonuniform red patterns distributed

on a bluish opalescent glaze surface with different tints. The blue Jun glaze was not colored by cobalt oxide, but was caused by the stronger scattering of the blue light with a shorter wavelength by the liquid droplet phase which fulfilled the size requirement for Rayleigh scattering. (Rayleigh scattering refers to the scattering of light off of the molecules of the air, and can be extended to scattering from particles up to about a tenth of the wavelength of the light. It is Rayleigh scattering off the molecules of the air which gives us the blue sky.) In other words, this was a kind of physical coloration. The copper-colored liquid phase droplets and cuprite formed the red patches, while the purple streaks were formed by the bluish polycrystals of chalcocite (Chen et al., 1983a, 1983b). The phase separation of the Jun kiln glaze was a physicochemical process taking place within a range of chemical compositions and under the actions of the firing temperature, atmosphere, and time. Because of complicated factors, it was difficult to control the formation conditions, so the appearance of the products could not be controlled easily; this was referred to as furnace transmutation.

Starting from the white-glazed porcelain manufactured in the Five Dynasties to the bluish-white-glazed porcelains in the Song dynasty, Jingdezhen has been one of the greatest kiln sites in terms of quality, quantity, and impact. Before the Yuan dynasty and the early Ming dynasty, there had been ground-breaking developments in the techniques required for Jingdezhen porcelains. The white-glazed porcelains of Shu Fu (Center government in Yuan dynasty) and the sweet white-glazed porcelains of the Yongle period were not only superb in terms of the quality and appearance, but also provided sound techniques and physics foundations for the further manufacturing of monochrome-glazed porcelains and polychrome-painted porcelains. Starting from the Yuan dynasty, Jingdezhen started to fire the blue-and-white underglaze colored by cobalt oxide and the red underglaze colored by copper oxide (CuO), as well as the blue-and-red. This started the manufacture of products with polychrome high-temperature underglazed colorants. In particular, the blue-and-white

porcelains were a unique long-lasting product with the largest sales in Jingdezhen. Furthermore, the different colors created by various metal oxides, such as iron, cobalt, copper, manganese, and their combinations, were the basis for the vibrant color-glazed porcelains from Jingdezhen. At the same time, overglazed painted porcelains started to emerge. When it came to the middle of the Ming dynasty, firing of the so-called *doucai* porcelains was successful, which incorporated the underglazed blue-and-white as well as overglazed paint. The best painted porcelains in the Ming dynasty were the *doucai* porcelains in the Cheunghua period, which were famous for their vibrant colors, white and moist appearance of the glaze, vivid patterns, and intricate skill work. They were collected in all major museums as well as by private collectors. In the Qing dynasty, there was another type of low-temperature overglazed painted porcelain called *wucui*. These were most famous during the Kangxi period. The subsequent *fencai* porcelains in the Yongzheng period also received great admiration.

After the Ming and Qing dynasties, major kilns all over China perished or stopped manufacturing, except that Jingdezhen kept firing its own colorful porcelains in large quantities and was able to imitate the products from other major kilns. In this way, Jingdezhen became the porcelain center in China and was nicknamed the “Porcelain City.”

The Dehua kiln in Fujian Province, which was developed some time later than the Jingdezhen, was also world famous for its high-quality white-glazed porcelains and sculpted porcelains. The semitransparent bodies of Dehua white-glazed porcelains, due to the relatively larger proportion of glass and the very thin glaze layer, made the Dehua porcelains uniquely bright.

Before the emergence of the polychrome underglazed painted porcelains in Jingdezhen, the dark brown underglazed painted porcelains colored by iron minerals and those colored by copper materials had already appeared in the Changsha kiln in Hunan Province and the Qionglai kiln in Sichuan Province during the Tang dynasty. These successes had far-reaching influences on the painted porcelains in

later generations. When it came to the Song dynasty, the painted porcelains manufactured by all the kilns in the Cizhou ware type in northern China reached another height. Since these were all folk kilns, the portrayed patterns were all derived from the daily lives of the general public, so the patterns had rich flavors of folk lives, which were in great contrast to those of the imperial wares with many more restrictions. These folk wares also created unique decorations which did not exist in the wares from other kilns.

From the proto-porcelains at the second milestone to the monochrome-glazed porcelains, polychrome-painted porcelains, and sculpted porcelains at the fifth milestone, porcelains dominated the history of Chinese ceramics. Interestingly, however, in Yixing, Jiangsu Province, which was also known as the *pottery city*, a world famous pottery called *Zisha pottery* (purple stone ware) has been manufactured since the Song dynasty.

Zisha pottery had many unique features. First, it was especially designed for tea drinkers. The most famous as well as the most manufactured products were teapots with various unique and beautiful forms. Second, it was derived from a unique raw material. The Yixing region is extremely rich in different kinds of Zisha minerals, which were used to produce Zisha pots with different colors. Third, most of the Zisha pottery were handmade, and made use of different tools in the manufacturing process, which fully reflected the wisdom and the skills of the pottery masters. Fourth, the decorations of the Zisha pots were unique in that they integrated the form, painting, poems, calligraphy, and seal cutting, and were thus very rich in Chinese culture characteristics. Starting from the Ming dynasty, there were great masters who made long-lasting famous pots. Therefore, Zisha pottery played a role in the fifth milestone.

When Chinese ceramic techniques developed into the fifth milestone, Chinese ceramics no longer referred to a single region or a particular monochrome-glazed porcelain. Instead, they included the monochrome-glazed porcelains, polychrome-painted porcelains, and sculpted porcelains from different kilns in both southern and northern China.

Ceramics in China,

Fig. 8 The scatter plot of the F1 and F2 factors for the chemical composition of the bodies of Chinese ancient ceramics

Three Technological Breakthroughs

The five milestones described above relied on continuous breakthroughs in firing techniques. The latter can be summarized as described below (Li, 1978a, 1978b).

Selection and Refinery of Raw Materials

The raw materials of pottery in general, particularly the early ones, came from the local soil. Therefore, the soil around the residences of early people became the raw materials for firing their pots. Since most of these people resided near hills or close to water sources, the collected raw materials were, in general, soils containing different sand grains. Early pottery was mostly sandy, containing different types of sand grains with different sizes. Strictly speaking, these soils were not suitable for firing pots. After a relatively long period of time, the people became aware that some soils might be more suitable for firing, and they started to select these soils for their pots. In other words, the people started to select the soils locally and clay pottery appeared as a result. When the people discovered that using a particular clay could not satisfy the requirements for forming, drying, and firing, they added different sand grains, ashes of vegetation, and shells of corn, as well as ashes of shells, etc., to get pottery including sand, charcoal, or mussel. The black

pottery including charcoal from Hemudu culture was a typical example (Fig. 3).

The raw materials for the stamped hard pottery, proto-porcelains, or even celadons and white-glazed porcelains were still selected locally. However, the people had higher standards for the suitable raw materials. This explained why the stamped hard pottery, proto-porcelains, and celadons were first successfully fired in some regions in southern China, while the white-glazed porcelains were first successfully fired in some regions in northern China. All in all, the raw materials derived from regions which were only suitable for particular types of ceramics.

Differences in raw materials will be reflected by the different chemical compositions of the ceramics. Principal component analyses have been performed on the chemical compositions of the bodies of 700 pieces of ancient ceramics spanning from the Neolithic Age to the Qing dynasty. The cumulative variance explained by the first three principal factors (F1, F2, F3) was more than 80 %. Figure 8 shows the factor loadings of F1 and F2.

From Fig. 8, we can clearly see the changes in the chemical compositions of ceramics in southern China. During the development from the stamped hard pottery to the proto-porcelains and then to porcelains, the silicon dioxide in

Ceramics in China, Table 2 Changes in the firing temperature of ancient ceramics

Product	Sample number	Highest firing temperature (°C)	Average firing temperature (°C)
Pottery	15	1,000	920
Stamped hard pottery	55	1,200	1,080
Proto-porcelain	37	1,280	1,120
Porcelain	146	1,380	1,240

the bodies increased gradually while the fluxing agents calcium oxide, magnesium oxide, and particularly iron oxide decreased. The contents of aluminum oxide did not change much until after the Song dynasty when the aluminum oxide contents increased due to the use of kaolin clay. The chemical compositions of the ceramic bodies had overlaps, which demonstrated their close relationships. However, the ceramics from northern China did not have this pattern. The northern Chinese pottery came from an area with high fluxing agents and low silicon dioxide contents, while the porcelains were in an area with low fluxing agents and high aluminum oxide contents. This is explained by the use of clay which is more readily melted as the raw material for the former and the use of clay with kaolinite as the raw material for the latter. The two regions were well separated, which showed that they had no relationships with each other. The chemical compositions of the small number of stamped hard pottery and proto-porcelain unearthed in northern China did not show any transitional zone between the two regions, so no relationships between their chemical compositions can be inferred. It can be said that the development from pottery to porcelain took a different path in northern China. However, the development from pottery to porcelain together with continuous improvements in their quality was primarily attributed to the selection and refining of raw materials. The raw materials were the fundamental substances for firing the ceramics.

Improvements of Kilns and Increase in Firing Temperatures

According to the vast amount of experimental data obtained for firing temperatures from

ancient ceramic shards, it can be concluded that there were two breakthroughs in firing temperature. The first one was realized for the firing of stamped hard pottery in the Shang and Zhou dynasties. The highest firing temperature of 1,000 °C and the average value of 920 °C for pots were increased to 1,200 and 1,080 °C, respectively. The second one was realized for the firing of white-glazed porcelains in northern China in the Sui and Tong dynasties. The highest firing temperature of 1,280 °C and the average value of 1,120 °C for proto-porcelains were increased to 1,380 and 1,240 °C, respectively, for white-glazed porcelains, the latter being the highest firing temperature for porcelains in the history of China. Table 2 summarizes the statistical data for the experimentally determined firing temperatures for pottery and porcelains.

From the archeological data for kilns, we can conclude that pottery from the early Neolithic Age might be fired without kilns, i.e., firing on the ground. Kilns were found from the Jiahu and Peiligang cultures. Kiln firing might have started later in southern China. After a long period of development and improvement, the dragon kiln and the chamber kiln with chimneys appeared during the Shang period in Zhejiang and Jiangxi Provinces. The stamped hard pottery and the proto-porcelain were fired in such kilns. The upward slope and the length of the dragon kilns, as well as the chimney of the chamber kilns, increased the drag force, thus enabling the rise in the firing temperature. This was the first breakthrough in the kiln structure, which facilitated the first breakthrough in raising the firing temperature.

In the Sui and Tang dynasties, big firing chambers, small kiln chambers, and multiple chimneys

appeared in Hebei Province in northern China. As seen from the above, improvements in the kilns were closely related to the increase in firing temperatures.

Invention and Development of Glaze

The earliest glaze which was transparent, bright, and which did not absorb water was the glaze for the proto-porcelains fired in the Shang dynasty more than 3,000 years ago. Therefore, glaze must have been created before the Shang dynasty.

It is well known that the proto-porcelains and the earliest porcelains were fired in southern China. Recently, a large amount of clay-glazed black pottery prior to the Shang period has been discovered in ancient kilns and tombs, and *Tao Yi* (pottery coat) has been discovered on the surface of colored pottery from the early Neolithic era in southern China. The creation and development of glazes in China can be divided into the following four stages, according to their chemical composition, microstructure, and appearance:

1. Breeding period of glaze – Shang dynasty
2. Formation period of glaze – Shang and Zhou dynasties
3. Mature period of glaze – Han, Jin, Sui, Tang, and Five Dynasties
4. Flourishing period of glaze – from the Song to Qing dynasties (Li, 1983)

Similar to the five milestones, the three technological breakthroughs signified improvements and achievements during the 10,000 years of history from the Neolithic Age to the Qing dynasty.

Contribution to Chinese Culture

Chinese ceramics have a long history, rich technological and arts contents, and are highly acclaimed all over the world. The contribution of ceramics to Chinese culture can be briefly summarized:

1. The early pottery was based on very simple techniques. Pottery techniques were an

Ceramics in China, Fig. 9 Schematic diagram showing the relic pottery kiln T31 in the Peiligang in Xinzheng, Henan Province

integral part of Chinese culture. These techniques were made up by the three stages of raw material selection, forming of the wares and the firing of the pottery. The basic ideas behind the whole set of techniques developed more than 10,000 years ago; they have been used until now, and have laid the foundations of ceramic industries in later generations. With pottery cooking utensils, the people could enjoy cooked food, which enhanced their quality of life. This is important not only for the Chinese culture, but also for world culture.

2. The Chinese culture is one of the four ancient cultures in the world (China, India, Near East, and Greece) that has been sustained until today, with the development of Chinese ceramics as an example of its sustainability.
3. Pottery kilns appeared in the relics of Peiligang in Xinzheng (Fig. 9) and Jiahu in Wuyang in Henan Province about 8,000–9,000 years ago (Kaifeng Managing Committee of Cultural Relics & Xinzheng Managing Committee of Cultural Relics, 1978; Zhang, 1999). These kilns proved that China was one of the first places to fire pottery in kilns. The appearance of kilns enabled the increase in the firing temperature (Table 3). This greatly enhanced the quality of the Peiligang pottery (Fig. 10) and at the same time enabled the first effective step in the history of high-temperature processes for mankind.

Ceramics in China, Table 3 Firing temperatures of some early porcelains from the Neolithic Age

Ceramics in China,
Fig. 10 Microstructure of a clay pottery of Peiligang in Xinzheng, Henan Province (70×)

4. Figure 10
5. Table 3
6. Slow wheel trimming for pottery appeared in the middle of the Yangshao culture, 4,000 years ago. Fast wheel trimming occurred during the Dawenkou culture. The fast wheel is also called the *potter's wheel*, which is the rudiment of the jolley (a mold to produce uniform hollow ware) used today. The fast wheel was a necessary requirement to throw as well as trim, and was instrumental in enhancing both the quality and the quantity of the products. The appearance of the fast wheel reflected the use of wheel shaft machines as well as the effects of inertia in manufacturing pottery, which inspired machining processes in later generations.
7. Early pottery contained certain amounts of sand grains with different sizes. Some of these sand grains occurred naturally in soils,

while others were purposely added. The latter ones were referred to as *Chan He Liao*. For example, the burned vegetation found in Hemudu pottery was purposely added (Fig. 3; Li et al., 1978). These additions were used to mitigate the contraction of clay during drying and firing, which served the same purpose as the clinker (a hard brick used as a paving stone) does today.

8. Pottery can be both containers and tools. Earthen spinning wheels, net weights, pills, and casts have been found in many relic sites of the Neolithic Age, which were tools for textiles, fishing, and pottery manufacturing. Despite the very simple forms, these served as the first examples of using pottery as tools, and demonstrated that pottery was an indispensable material in human lives. In particular, the earthen pills and earthen net weights not only signified the exploitation of elastic stress and gravity machines in the manufacturing process, but they also illustrated that pottery needed chemical reactions, which were unlike stone wares which needed only physical processing. This was pioneering in the chemical industry.
9. Pottery was the earliest product integrating technology and arts. Colored pottery was discovered in Jiahu in Wuyang, Henan Province as well as in Hemudu, Yuyao, Zhejiang Province. Colored pottery and pottery statues were also found for the late Neolithic Age. These not only showed the artistic talents of the people, but also reflected their daily lives. For example, carved symbols were found on pottery from the relic site of Jiahu, which provided information on the emergence of Chinese words. Colored pottery was an ancestor to polychrome-painted porcelains in later generations; pottery statues were ancestors to sculpted porcelains.
10. The crucibles for alloy melting for bronze wares and the pottery moulds for casting illustrate the required skills for techniques. The emergence of pottery kilns and the attainment of higher firing temperatures as a result of the improvements in the kilns facilitated the development of bronze wares and thus the early arrival of the bronze-ware era. The early pottery marked the start of the Neolithic Age, but improvements and extended applications played an indispensable role in marking the end of the Neolithic Age and in marking an unacknowledged ceramic Age.
11. Porcelains are recognized as one of the greatest inventions in China. The manufacturing techniques of porcelain masters in different times were adopted by different countries in Europe and Asia, which had significant influence on the manufacture and the development of porcelains in certain countries in the world.
12. One of the main reasons that the Jingdezhen porcelains could survive and their quality improve was that the recipe contains kaolin clay and its percentage kept increasing. The good quality of the white-glazed porcelains from the Xing Kiln in northern China starting from the Tang dynasty was also attributed to kaolin clay. Firing of hard porcelains in Europe was also successful after the use of kaolin clay. China was the first country to discover kaolin clay. The terms *kaolin clay* and *kaolinite* were translated from Chinese.
13. The famous porcelains manufactured in various areas in China not only satisfied the needs of different people in China, but were also exported in large quantities or used as precious gifts. These exquisite porcelains, as part of Chinese culture, were thus dispersed to different areas in the world. This inspired their techniques and at the same time built the reputation of Chinese porcelains over the world.

Ceramics in Korea

Carolyn K. Koh Choo
Chung-Ang University, Seoul, South Korea

Korean ceramics is a culture that has been close to the hearts and minds of Korean people throughout its history. In many parts of the country, one can still touch the centuries-old remnants of everyday bowls and dishes and even artistic masterpieces. For those who seek them out by research or consulting with experts and village elders, waste mounds of shards and dragon kilns are invariably found on sunny mountain slopes with flowing brook water nearby. Such artifacts reveal many details of the forming, designing, and firing methods of traditional Korean ceramics.

Today, Korean ceramics is enjoying an active phase of development. For the first time, all four major types of pottery – *togi*, celadon, *punch'ŏng*, and whiteware – are produced simultaneously in numerous studios. With the continued unearthing of kiln sites in major excavations have come new

theories about the rise and development of Korean ceramics history. The overseas museum space dedicated to exhibiting ceramic art pieces has increased noticeably in the last decade. Special fairs, biennales, and competitions are held in many locations that attract both Korean and international audiences. The World Ceramic Biennale, held in 2005 for the third time in the greater area of Kwangju (near Seoul; this was the center of ceramic activities during the Chosŏn dynasty), is developing as an important event for ceramic arts and crafts.

Coming of Age for Korean Hard-Paste Porcelain

Among countless types of ceramic products that make ceramic culture ubiquitous, the position held by Korean porcelain and stoneware is due to their hard-paste raw material. Korea and China were the first countries to possess the know-how for using this material, readily available in nature, and obtaining the necessary firing power for its proper vitrification (forming a glassy or noncrystalline material). Although the dates are still being debated actively among ceramics scholars, a long tradition of making high-fired unglazed stoneware, called *togi*, enabled Korea to adopt porcelain technology from China sometime between the early ninth and late tenth centuries. The making of refined teabowls must have been a strong motivation for the import of the technology because shards of such bowls are found in abundance in early kiln sites. The Japanese porcelain industry began only after many Korean potters were taken to Japan during the Hideyoshi Invasion (1592–1598), which is also known as the Ceramics War or the Tea Bowl War.

While China and Japan benefited enormously from the export of their porcelain wares to Europe until the technology successfully developed there in the eighteenth century, Korea maintained its unique aesthetics that were appreciated mainly within East Asia. Never developing the overglaze that was so popular in Europe, Korea produced one major type at a time: *togi*

up to the Unified Silla Kingdom (AD 668–935), celadon during the Koryŏ dynasty (AD 918–1392), and *punch'ŏng* and then more commonly whiteware during the Chosŏn dynasty (AD 1392–1910). Although several other types were also produced – including a substantial amount of white teabowls in the initial stages of porcelain technology, a small amount of black temmoku type, and a very small amount of ware known as Chosŏn celadon with white body and celadon-type glaze – the linear sequential development of the four major types is undeniably the predominant feature of Korean ceramics history.

It is not surprising, therefore, that Korean ceramics remained largely unknown in the world, as attested by Bushell's report in his comprehensive 1896 book *Oriental Ceramic Art*. "Korea has been thoroughly explored during the last few years, and it is now known that no artistic pottery is produced there in the present day, and no indisputable evidence of any original skill in former times has been discovered." Within a decade of this report, an enormous amount of porcelain (including thousands of pieces in many shapes and types) was unearthed during the building of railroads. Many accolades were bestowed on Koryŏ *pisaek* celadon as early as the twelfth century. For example, a Song connoisseur, Taipyŏng Noin, said they were the "First Under Heaven," and a famous calligrapher envoy to Korea, Sŏh Keung, referred to the celadon as being very refined with workmanship surpassing that of the Yüeh kiln (in China). The isolation of Korea from development in other parts of the world resulted in the unique characteristics of simplicity and quietness that today are acclaimed as the quintessence of oriental spirit.

Togi Up to the Unified Silla Kingdom

The term *togi*, with a literal meaning of earthenware or clayware, is used inclusively for a wide variety of mostly unglazed earthenware or stoneware produced from the beginning of the Neolithic Age (ca. 6000–1000 BCE) through the Bronze and Iron ages (ca. 1000–0 BCE), the proto-Three Kingdoms period (ca. AD 0–300),

Ceramics in Korea, Fig. 1 Long-necked jar. Black pottery. Excavated at Kijong-dong, Taejeon. Bronze Age. National Museum of Korea, Seoul

the Three Kingdoms period (ca. AD 300–668; Koguryo in the north, Paekche in the southwest, and Silla in the southeast), and much of the Unified Silla Kingdom. On a much smaller scale, the production of *togi* continued during the Koryŏ and Chosŏn dynasties. One of the oldest Korean ceramic wares known today, a reddish comb-patterned jar with a pointed bottom, is carbon dated to 5770 BCE. Red and black (Fig. 1) pottery from the Bronze and Iron ages attests to the high-level technology and aesthetics that the ceramic culture already obtained. These soft-textured wares were painted with iron pigments and burnished and most likely fired in an open pit.

By the end of the proto-Three Kingdoms period around the fourth century, two breakthroughs allowed the technology to become much more sophisticated and efficient. The potter's wheel was introduced, and the knowledge of high firing power, originally developed for bronze and iron casting, was applied to ceramics production. The type of dragon kilns and the method of reduction firing that Korea used continuously throughout its ceramics history were developed at this date. The *togi* fired in this way was highly vitrified and hard textured to the extent that it rings like porcelain when struck with the fingers. These wares were colored usually blue gray or black gray.

Ceramics in Korea, Fig. 2 Map of Korea with historically important kiln sites and capital cities of different dynasties. Kaesŏng is the capital city of the Koryŏ dynasty (AD 918–1392), Kyŏngju that of the Unified Silla Kingdom (AD 668–935), and Seoul that of the Chosŏn dynasty (AD 1392–1910) as well as modern Korea

The first of these grayish stonewares is known as Kimhae ware after the southeastern area where they were first produced (Fig. 2). Kimhae prospered as an independent state known as Kaya until absorbed into Silla in the sixth century, and the highly vitrified *togi* characteristic of this area is also referred to as Kaya *togi*. Such ware became more refined and was produced in such vast amounts during the Three Kingdoms period and Unified Silla Kingdom that they are found in abundance even today.

The forms of the *togi* bowls and jars already possess the elements of beauty that characterize

Korean ceramics in general, especially the slender gracious line of Koryŏ *maep'yŏng* and the voluptuous roundness of Chosŏn whiteware jars. Both of these elements make the Kaya pedestalled jars, usually with lids, very attractive. The tall and short pedestals are basic components in much of the *togi* form. Shaped either as part of the whole ware or separately, they often have beautiful contours.

The naturalistic forms of humans, animals and birds, transportation means, and houses were favored motives both as shapes and as decorations. There were many varieties of warriors mounted on horses or carriages (Fig. 3). A roof-end tile, in spite of its monstrous appearance, stimulates the feeling of warmth that is a hallmark of Korean ceramics (Fig. 4). A handsome inkstone is a forerunner of small equipment for calligraphy, which was made both in the Koryŏ and Chosŏn dynasties (Fig. 5). A Silla long-necked jar is decorated with many symbols of fertility and well-being, such as figurines of a snake, a frog, a bird, a duck, a turtle, a woman playing a *kayakum* (a traditional musical instrument), and a man and a woman engaged in a sexual act.

The Unified Silla wares with lead and tricolored glazes of the Tang style are rare examples of low-firing glazes, because they were discontinued in the following Koryŏ dynasty (Figs. 6 and 7). Why Korea stopped this line of development and never adopted or developed the lead-containing materials for overglaze decoration that became so popular and profitable in China and Japan is one of the most interesting questions concerning the Korean ceramics industry.

Some later *togi* wares were glazed, often only partially, but this occurred due to ash falling on them unintentionally in the process of wood firing. Recent excavation of an eighth- to ninth-century *togi* site at Kurimni in the southwestern area near the important celadon centers of Kangjin and Haenam offered some circumstantial evidence of glaze being intentionally applied. Such a suggestion is a topic of interest, because it raises the possibility that celadon technology might have arisen indigenously within Korea.

Celadon in the Koryŏ Dynasty

The appreciation of Korean ceramic art usually begins with numerous celadon masterpieces in the shape of *maepyŏng* vases, which inherited from the *togi* tradition the graceful elegant contours of the pedestalled jars and other vessels. This type developed widely and artistically with many variations in the shape and styles of decoration. The earlier ones decorated with only incised designs are often *pisaek* and beautiful. Many were decorated with inlaid designs of clouds and cranes (Fig. 8), and some rare pieces were painted with iron-black slip before the

glazing (Fig. 9). The gourd-shaped ewer with decoration of copper red is a variation in shape (Fig. 10).

The love of naturalistic forms of plants, animals, and birds was also inherited from the *togi* tradition. Notable among them are many water droppers, such as a child holding a bottle and a monkey holding a jar as big as itself (Fig. 11). An ewer in the shape of a dragon-headed tortoise seated on a lotus pedestal (Fig. 12) and an incense burner with the lid and feet in the form of lion figures (Fig. 13) are some of the celadon vessels with elaborate naturalistic forms.

Another form that was dominant in the Koryŏ dynasty was the teabowl (Fig. 14), as the act of drinking tea was a highly valued means to clear one's mind for meditation in the Buddhist Koryŏ dynasty. The teabowl shards excavated in the

earliest porcelain kiln sites have a particular style of wide foot rim that resembles the sun's halo and is called, in Korean, *haemurigup*. The similarity in these foot rim styles, glaze colors, and general shapes of these wares with those found in Yüeh kiln is one of the reasons to believe that the Korean porcelain technology was strongly influenced by the Chinese technology or even that it was directly imported from China (Fig. 15).

Haemurigup teabowls in recent excavations included surprisingly both celadon and whiteware. In particular, a series of excavations in Sōri and Bangsandong in the 1980s and 1990s near Seoul showed that whiteware was just as important as celadon in the earliest stages of

porcelain technology in Korea. During the latter part of its two-century-long production, Söri produced only whiteware, and another nearby site of Chungamni also produced mainly whiteware during its entire existence.

Ceramics in Korea, Fig. 12 Celadon ewer in the shape of a dragon-headed tortoise seated on a lotus pedestal. The head, body, and twisted lotus-stem handle are modeled. First half of the twelfth century. Height 17.0 cm. National Museum of Korea, Seoul

Söri, Bangsandong and Chungamni were among some 50 sites located inland in the western midsection of the country, and they are now considered one of two distinct routes of technology transfer from China. The other route consists of a group of sites in the Kangjin area on the southwestern coast. These two different routes show several remarkable differences. Unlike in

the inland kiln sites, only celadon is found in Kangjin. From the beginning, Kangjin kilns were constructed with mud and rock in a similar style to *togi* kilns, while kilns in inland sites were first constructed with bricks as in some Chinese kilns. Only later was the Kangjin-type kiln of mud and rock introduced to some of the longer running inland sites such as Söri. Kangjin fired the wares in two steps – once before and again after glazing – while inland kilns fired wares in one step like the Chinese.

Ceramics in Korea, Fig. 14 Celadon bowl with inlay decoration. Mid-twelfth century. Height 6.4 cm. National Museum of Korea, Seoul

By the middle of the eleventh century, the inland kilns were mostly closed, while another center at Puan about 200 km north of Kangjin was newly established. The founding of Puan and closing of the inland kilns represented a new and indigenous phase of porcelain technology. In the two centers of Kangjin and Puan on the southwestern shore, porcelain production became highly centralized and reached a high technical and aesthetic level. Dedicating their efforts only to celadon rather than producing several styles, Koryŏ potters and their patrons made three original achievements in ceramic arts and crafts: *pisaek* glaze, the decorative technique of white and black inlay, and that of copper red.

Pisaek, represented by two different Chinese characters, mainly appears in a jade color and kingfisher's color (after the bird's blue-green plumage) in Korea and as a secret color in China. In the Koryŏ *pisaek* celadon, the thin glaze blends with the body of the ware, revealing it just enough that the observer yearns to see more. Chung Yangmo, a leading historian of ceramic arts and former director of the Korean National Museum, likened the Korean celadon glaze to clear water flowing through

Ceramics in Korea,

brooks and streams in the mountains and valleys and to a partition screen made of ramie fabric.

The thin transparent glaze that showed off the celadon body in a harmonious way was ideal for underglaze decorative techniques. Perhaps such a success enabled and motivated Koryŏ and later Chosŏn potters to persist with only underglaze decorations. The first decorative effect was achieved simply by incising figures such as flowers and birds or making them stand out in relief. The second of the three achievements was made when the incised lines were filled with white or red (which turns into black when fired) clay material to contrast with the gray body color. Flying cranes among stylized clouds (Fig. 8), ducks playing underneath plants such as willow trees and reeds, and various renditions of lotus, chrysanthemum, and peony flowers are some of the inlaid designs.

The third original achievement was the use of copper red, and this represented a technical challenge that required a good control of firing atmosphere and schedule. The volatile copper turns green when oxidized to its divalent state of cupric oxide (CuO). By the first half of the twelfth century, the subdued red from the reduced state of cuprous oxide (Cu₂O) and copper metal in colloidal state was used only sparingly in most cases to represent grapes (Fig. 10) and peony sprays (Fig. 16). It was used to outline lotus petals in gourd-shaped ewers and to cover the entire ware (Fig. 17).

Though the predominant wares were glazed gray green or blue green similar to *pisaek* celadon, some unusual glaze and decorative methods were produced. The entire body of *maep'yŏng* (Fig. 9) is first coated with black pigment and decorated by brush painting with white slip before a clear glaze is applied. Another type is colored light brown, most likely to have been fired in an oxidizing atmosphere. Often it is brush painted with iron pigments and resembles Cizhou wares. Even a small amount of porcelain whiteware, in general much more vitrified than the whiteware teabowls of the earliest stage, was produced at Puan (Fig. 18).

Punch'ŏng and Whiteware in the Chosŏn Dynasty

Punch'ŏng grew directly out of inlaid celadon in the last decades of the Koryŏ dynasty when the government became too weak to keep the ceramic activities supervised and centralized. In the first two centuries of the Chosŏn dynasty, *punch'ŏng* blossomed into a folk craft and art

Ceramics in Korea, Fig. 18 White porcelain *maepyo*, decorated with black and white inlaid floral designs. Mid-twelfth century. Likely to have been made in Puan. Height 28.8 cm. National Museum of Korea, Seoul

that was unique to Korea. Some of the earliest pieces are difficult to differentiate from heavily inlaid celadon. The white slip material was eventually coated or brushed over the entire body surface before any further decoration was applied (Fig. 19). The name *punch'ong* was coined for this type of ware by Koh Yusŏp, a scholar of Korean ceramics in the first decades of the twentieth century, and was adapted from the longer term, *punch'ong* (powder-decorated) *whe-ch'ong* (gray-blue) *sagi* (stoneware). The white slip was first used as a decorative medium easier to apply than white inlay, but eventually it became a means to make the wares appear whiter to meet the demand of royalty and officials who favored heavily the whiteware. The production of *punch'ong* came to an abrupt end after the Ceramics War. With so many potters taken to Japan, only the whiteware production was revived afterward in Korea.

Punch'ong is vigorous in form and decoration modes. Unlike celadon, it was produced in all parts of the country, and different styles reflected the people's daily lives, rooted deeply in the earth and other natural environments. The free-spirited spontaneous flow manifested in *punch'ong* led

Ceramics in Korea, Fig. 19 *Punch'ong* jar with lid. Arabesque design painted in underglaze iron. Sixteenth century. Height 17.2 cm. National Museum of Korea, Seoul

Koh Yusŏp to characterize Korean ceramics as made with “a plan without planning” and “technique without technicalities.”

Celadon inlaying techniques became modified in many ways. The incision of designs was replaced by stamping with engraving tools or even with rope. Instead of filling individual incised lines or surfaces with inlay material, white slip was applied on the whole stamped body. When the body and the slip were leather dried, the surface was scraped off evenly with the stamped areas left with white inlay. In another modified method, all the areas except those of such designs as flowers and plants were scraped off. Sometimes the scraped background was painted with iron-rich clay to contrast with the decorative area.

In more casually made wares, the only decorative element was white slip that was applied freely and unevenly with a large coarse brush. The abstraction of designs is bolder and more freely executed when they are brush painted with iron-rich pigment over white slip (Fig. 19). Those made in such styles in the area of Keryŏng Mountain became particularly popular with the Japanese.

Together with *punch'ong*, white porcelain replaced celadon as the dominant type in the Chosŏn dynasty. Chosŏn potters were able to produce much more vitrified whiteware than Koryŏ counterparts by adopting the two-step

firing method that Kangjin and Puan had developed and used throughout their celadon production history. The adoption of Confucianism and its stern frugality from the Ming dynasty as the guiding principle of the new society to replace the Koryŏ lifestyle of pleasure and luxury provided the crucial force for the ascent of the whiteware technology. The undecorated pure white was preferred, and the decoration was again limited to underglazing. The import of cobalt blue from China to produce white and blue represented the only innovative element in the new Chosŏn technology.

The raw material for Chosŏn whiteware was rediscovered in the area nearby Sŏri and Bangсандong, two centers where Koryŏ whitewares were produced at the beginning stage of porcelain technology centuries earlier. Except for the lower contents of iron and titanium oxide, it is basically the same porcelain stone that is used for celadon. This general area with plentiful raw material, Kwangju near the ruling center in Seoul, was soon established as the official kiln for producing high-quality wares for the use at court. In much the same way as in Kangjin and Puan, the ceramic activity in Kwangju was supervised and centralized by court officials for nearly 500 years. So far some 285 sites have been discovered in this area, where the potters had to move to new sites approximately every 10 years in search of firing wood. Unlike celadon, the production of whiteware, however, was not restricted to this area and was produced all over the country.

The majority of Chosŏn whiteware was undecorated. As mentioned before, the colorful overglaze decoration was never developed, and even the underglaze decoration with cobalt, iron, and copper oxides was sparingly used. However, the various shades of white for body and transparent glaze, combined with beautiful forms, resulted in some of the most appreciated masterpieces. The eighteenth-century jar with globular body is representative of such pure white, imparting the feeling of abundance and warmth (Fig. 20). This particular form is made in diverse modifications and decorated with various designs and colors. The brush painting with cobalt blue

Ceramics in Korea, Fig. 20 White porcelain jar with everted lip and globular body. Late seventeenth century. Height 40.8 cm, National Museum of Korea, Seoul

Ceramics in Korea, Fig. 21 Blue and white jar with cloud and dragon design. Second half of the seventh century to early eighteenth century. Height 35.3 cm. National Museum of Korea, Seoul

on a late seventeenth-century or early eighteenth-century globular jar is executed freely and boldly in the same characteristic manner as *punch'ŏng* wares (Fig. 21).

The cobalt blue decorated wares, made mostly for royal use, are usually refined and restrained. The cobalt pigment, imported and expensive, was usually used sparingly (Fig. 22). When its use became even more difficult after the war with Japan, iron pigment was substituted as the main pigment. It was used more freely and effectively in various styles of brush painting, some refined and some very daring (Fig. 23). The use of copper red, which became more liberal in the eighteenth and nineteenth centuries, produced various styles of jars, bottles, and water droppers that are very

Ceramics in Korea, Fig. 22 Blue and white porcelain angular bottle with orchid design. Second half of the seventeenth century. Height 41.5 cm. National Museum of Korea, Seoul

Ceramics in Korea, Fig. 23 White porcelain bottle coated with underglaze iron. Second half of the eighteenth century. Height 27 cm. National Museum of Korea, Seoul

free spirited (Fig. 24). In some rare pieces, two of the three pigments are used in combination, and very rarely all three pigments are used, always very sparingly.

Ceramics in Korea, Fig. 24 White porcelain water dropper coated with underglaze copper red with molded double crane design. Nineteenth century. Height 5.4 cm. National Museum of Korea, Seoul

This short treatment of 8,000 years of Korean ceramic art and culture, linearly developing *togi*-celadon-*punch'ŏng*-whiteware as distinct phases of creative and original achievements, leaves many important stories untold. Many teabowls of the Koryŏ and Chosŏn dynasty that became national treasures in Japan and the brown pottery known as *onggi*, which ranges from small boilers for herbal medicines to enormously large storage jars, are important examples that have been omitted altogether. The masterpieces and coarse everyday utensils are testimony not only to the availability of diverse materials and technical know-how of Korean potters and their clients but also their creative spirits, their love of nature, and their dreams and ideals.

Scientific Study on Traditional Korean Ceramics

Within Korea the scientific study of Korean traditional porcelain began about 25 years ago in the late 1980s. The first such work was presented internationally in 1992 in the Proceedings of Material Science Society of America. Chinese ceramics had been an academic subject of scientific investigation and analysis for almost a century in several western countries such as Sweden, England, and America and eventually in China itself. Some of the important results culminated in the first proceedings of the international

symposium in 1982 organized by the Shanghai Institute of Ceramics and several volumes of *Ceramics and Civilization*, edited by MIT's W. D. Kingery. Serious analytical works abroad on Korea began in the 1980s by scientists like Pamela Vandiver and Richard Newman in America, Nigel Wood in England, and K. Hangst in Germany.

One of the preparatory aspects of the Korean study was to locate the waste mounds of shards, kiln equipment, and clumps of fired clay left at the original production sites. It was not easy to find them any more, as the kiln sites were erased out of existence to make room for cultivating fields, houses, roads, and dams. After endless inquiries in books and to village elders, one still can be lucky to find them tucked away quietly, along mountain edges with water streams flowing nearby. The spots are invariably sunny and beautiful like the ones that must have been sought after ardently to bury loved ones, as graves are often found close by. The shards chosen as representative ones in such sites were the first ones to be analyzed in the initial stage when various experimental methods were tested and established for the new study.

Soon the community of ceramic historians and archaeologists joined the effort to understand Korea's ceramic heritage from scientific and technological points of view. Well-documented shards from systematic excavations and surface investigations by leading museums and ceramic studio institutes were donated, enabling the analysis work to become systematic with the possibility to connect the results with artistic functional features. For this reason archaeological information and visual features of the shards were recorded meticulously before they were analyzed for their compositional and microstructural characteristics.

The work was initially led and centered at a laboratory in the Department of Scientific Studies of Cultural Heritage in Chung-Ang University but quickly spread to several other centers. Eventually more than 1,500 shards of celadon, punch'ŏng, and whiteware were collected and studied in Chung-Ang University alone, where they are organized by ceramic types, locations,

and periods of their production and stored for further studies. From these studies were worked out the developmental changes of the ceramics from celadon to punch'ŏng, and to whiteware, and these were presented in a series of three papers in English in a Korean journal named *Journal of Conservation Science*.

Body Composition

Regardless of the ceramic types, a predominant proportion of the Korean bodies was formed with a hard-paste clay material called pottery stone or porcelain stone. Such is the case in southern China, too. This material is an intermediary type of clay formed during the disintegration process from igneous rocks of feldspar into kaolinite. In the process, the alkali oxides of Na_2O and K_2O from feldspars are leached out until pure kaolinite ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$) is formed. Feldspars do not have plasticity to be formed into bodies, and plastic kaolinite is so highly refractory that it requires an extremely high firing power to vitrify. However, porcelain stone in the mid-stages contains various minerals in a wide range of concentrations in such a way that they can be used as they are found with only the physical processes of powdering and purification.

In the process of transformation, hydromical clay is formed in such mineral forms as muscovite, illite, and sericite, and even a small amount of primary kaolinite. Hydromical clays are plastic due to the mineral structure of their sheets in a similar fashion to mica; they also have fluxing property from the alkali oxides still retained in them. In addition to the newly formed clays, porcelain stone from the intermediary stages contains the remnant feldspar and the original quartz. These various minerals make the porcelain stone become triaxial, as they contain all three different properties to form and vitrify ceramic bodies. The plasticity of hydromical clays and a small amount of kaolinite allows the clays to be formed into various shapes, the fluxing property of hydromical clays and feldspars makes the bodies to be vitrified, and the refractory quartz retains shapes as the bodies are fired and become molten at high temperatures. Porcelain stone from earlier stages is sometimes referred to as glaze stone

because higher amount of feldspar still retained makes the material have a higher fluxing property and thus make it appropriate as the flux component in making glaze batches. Often glaze stone is found finer grained than porcelain stone.

The porcelain stone and glaze stone are found in abundance in Korea as in southern China. There is a geological dividing line called Nan Shan Quiling that runs in a west–east direction roughly midway between the Yellow River and Yangtze River in China. This line extends up northeast to Korea, and south of this line porcelain stone is found in abundance; in the north there is kaolinite. Therefore, the majority of Korean and southern Chinese wares from such kilns as Yüeh kiln, Jingdezhen, and Dehua are made with porcelain stone. On the other hand, the northern wares from such kilns as Yaozhou, Ding, and Linru are formed with kaolinite and fired at higher temperature around and above 1,300 °C.

Among the Korean ceramic bodies so far analyzed, only shards that may have been formed from kaolinite are the late fifteenth-century whiteware shards from local kilns of Chunghyodong and Yonggye-ri in Jeolla South Province. Chunghyo-dong had been successfully producing punch'öng for half a century before attempting to make whitewares in around the 1450s. Their first whiteware was soft textured, because their firing power was far too low to vitrify the bodies formed of kaolinite clay. Only about 20 years later, it succeeded in vitrifying properly because they added to the kaolinite some glaze stones particularly rich in albite, Na₂O-based feldspar. Adding glaze stone to bring down the firing temperature of kaolinite bodies had occurred more than a century earlier at Jingdezhen in China during Yuan dynasty (1279–1368), but such a practice was not common in the fifteenth century. At present nothing is known about how Chunghyo-dong potters were inspired to use such an innovative material or whether such material was used significantly in whiteware kilns of later times. To date only a limited number of later kilns in rural areas have been excavated, and eighteenth- and nineteenth-century kilns have been excluded from the

collection of 1,500 shards so far analyzed at Chung-Ang University.

The porcelain stones appropriate for different ceramic types contain different levels of iron oxide and titanium oxide. Ideally the material for whiteware should contain as little of Fe₂O₃ as possible, and in Chinese its level was mostly less than 0.5 wt%. Unfortunately, Korea lacked such pure material, and in some whiteware shards, as high as 2 wt% level was often found. In general its level in whiteware ranged between 1 and 2 wt%, in celadon between 2 and 3, and in punch'öng between 2.5 and 4. In the similar way, the level of TiO₂ should be nearly zero for whiteware, but in Korean whiteware as much as 0.4 wt% has been found. In celadon and in punch'öng, the presence of certain amount is needed to make the body fire to gray, and its level was found in the range between 0.5 and 1.0 wt%.

Glaze Composition

Traditional Korean glazes are high-fired glazes formulated by mixing two different types of material, clay and flux component, as was the case with the majority of southern Chinese kilns. Within this system of two components, changes occurred over Koryŏ celadon and Chosŏn whiteware glazes. Although certain punch'öng kilns initiated change that eventually became established as normal whiteware practice, punch'öng wares kept many of the celadon practices well into the newly found Chosŏn dynasty.

Calcium oxide was the chief flux ingredient in all but a few cases, and it was provided in the form of wood ash, burnt limestone, or powdered limestone. The level of phosphorus oxide P₂O₅ in the glaze composition is a good indicator whether and how much wood was involved in the preparation of the flux material. Wood ash was the earliest traditional flux material, and in some Korean porcelain, it is likely to have been added by itself to the clay component. In an extensive compositional analysis study, Sŏri is found to have been such a center. Both celadon and whiteware glazes from Sŏri complex contained P₂O₅ in high levels above 1.5 wt%.

In the majority of Koryŏ glazes, however, P_2O_5 is found in a concentration range between 0.5 and 1.0 wt%. Meanwhile, CaO is found in a high concentration range between 15 and 22 wt%. Such a small ratio of P_2O_5 and CaO implies that burnt limestone and not wood ash was employed as the main flux material. Known as glaze ash, the burnt limestone was an ideal flux material especially for the high-lime glazes with limited level of phosphorus, which were used persistently at Kangjin and Puan, the centers of inlaid celadons. High-lime glaze becomes transparent when fired to high temperature and cooled rapidly, and a moderate amount of bubble created by limited level of P_2O_5 in glaze ash makes the glaze become somewhat translucent. Such glaze shows off the underglaze decorations of incised and inlaid designs quite clearly and at the same time softens the images. The centers of the inlaid celadon of Kangjin and Puan used this high-lime glaze with a limited level of P_2O_5 persistently. Sometimes burnt shells may have been used, too, as they are found easily in these complexes in southwestern coastal areas.

In many cases of celadon, burnt limestone may have been supplemented with wood ash. *punch'ŏng* wares produced from the last decades of the Koryŏ dynasty in fourteenth century until the early decades of the sixteenth century in Chosŏn dynasty continued to employ celadon methods of obtaining flux material by burning wood by itself for wood ash or burning limestone to make glaze ash. However, in making whitewares at the royal complex in Kwangju, such a practice of using wood disappeared, only with a few exceptions of the early fifteenth-century kilns, where a special ceramic type known as Chosŏn celadon was made as one of their regular productions. These wares were made of whiteware bodies but had celadon glazes, whose flux continued to use the celadon tradition of using wood in some capacity. A low level of P_2O_5 around 0.2 wt% was detected in their whitewares, but in kilns of the late fifteenth and early sixteenth centuries, it is no longer detected. By such time the important change of using limestone in its powdered form had occurred.

Another important change accompanied the change to a powdered form of limestone. Less flux was used, making the concentration of CaO decrease to about 15–10 wt% from the range of 15 to 20 in celadon. Instead the concentration of alkali oxides, Na_2O and K_2O , increased. In the scheme of categorizing high-fired glaze types according to the concentration of CaO and alkali oxides into four types of high lime, lime, lime alkali, and acid rock, the Kwangju whiteware glazes ranged between lime and lime alkali, changing from celadon glazes that ranged between high lime and lime. The latest kiln sites of official Kwangju complex Geumsa-ri and Punwŏn Village of the eighteenth and nineteenth centuries where blue and white were produced increasingly in greater quantity used the lime-alkali type. This type had become the favored one at Jingdezhen in China, too, as it is rather viscous and does not diffuse the cobalt decorations as much as glazes with a higher amount of calcium oxide. Geumsa-ri complex is acclaimed for having produced some of the most beautiful whiteware, especially those with snow-white or milk-white glazes. The fine quality of its glaze composition may be in some way due to an unusually high level of MgO around 4 wt%, more than double the usual amount.

As for the clay component in glaze formulation, often slightly different forms of clay like glaze stone instead of the clay used for the body itself was employed. The relative levels of titanium oxide in the glaze and body have been a good guide to decide which. In Yüeh kiln, one of the most influential Chinese kilns to Korean ceramic technology, the TiO_2 content in the glaze was found to be usually about 80 % of that in the body. Such a compositional characteristic resulted from the practice of mixing body clay with flux material in proportions around 8:2. Such a consistent proportional relationship was not found in Korean glazes. In Bangсандong and Sŏri kiln sites, its level in whiteware glaze was slightly higher than that in the body. A similar situation was observed for iron oxide Fe_2O_3 . On the other hand, in Kangjin complexes the level of TiO_2 in the glaze was only about one third of the level in the body.

Clearly such levels of TiO_2 content in Korean glazes could not have been obtained by using the body material itself. It is logical that glaze stone was used in Korean glazes, because it has the same characteristics as porcelain stone, except it has more alkali oxide content and is in general finer grained. What is surprising is that it was employed from the very beginning stages of Korean porcelain, as practiced in the earliest kiln complexes as Bangсандong, Sŏri, and Yongun-ni of Kangjin.

Glaze stone is a versatile material with a wide range of composition, which would depend upon various factors such as the composition of the original mother rock and the particular stage of transformation when it is found. A wide compositional range enabled potters to search for and choose a batch of glaze stone appropriate for their particular wares. There is also a possibility that glaze stone was used together with the body material of porcelain stone in order to bring about the desired effect that the potters were looking for. For their whitewares, Bangсандong and Sŏri potters had to find glaze stone that was almost free of TiO_2 and Fe_2O_3 except in the smallest concentrations of a few tenth of a weight percent. For their celadon glazes, Kangjin potters needed glaze stone with the TiO_2 content around 0.4–0.5 wt%, about half of the level found in celadon body material. Fortunately, such ceramic materials with similar compositional characteristics were available rather easily at close distances, as the Kangjin area had not only an abundance of celadon materials but also mines of porcelain and glaze stone with such low TiO_2 content that they could well have been used to make whitewares. Actually such a mine exists to this day in front of Jŏngsusa, a temple that used to be the spiritual center of celadon potters.

When the new Chosŏn dynasty began, glaze stone as free of TiO_2 and also of Fe_2O_3 as possible was adopted both for whiteware and punch'ŏng. Such a selection is expected for whiteware, but it is quite surprising that even punch'ŏng glazes followed the same change while keeping other characteristics similar to those of celadon. The range of Seger values of SiO_2 and Al_2O_3 and also the levels of P_2O_5 and

CaO contents in punch'ŏng were similar to those of celadon. The practice of burning limestone and using it as a flux component by itself or in combination with wood ash lasted much longer in making punch'ŏng glazes than in making whiteware glazes, for which limestone was soon powdered.

Another characteristic of the glaze stone adopted for the lime and lime-alkali glazes of the Chosŏn dynasty is its increased content of alkali oxide. Such glaze stone is an earlier product in the process of transformation from the original feldspar state into the final kaolinite state. A pronounced form of early product rich in feldspar content, especially albite, was used at Chunghyo-dong in the middle of the fifteenth century in developing a glaze with a composition close to acid rock. The combined content of Na_2O and K_2O was higher (8.42 wt%) than the content of CaO (7.01 wt%). Such a unique glaze composition was not observed anywhere else in Korea until then, and only at another contemporary kiln nearby at Yonggye-ri. As with the case of innovative Chunghyo-dong bodies, whether such a new type of glaze was used significantly in later kilns is not known at the present time, since eighteenth- and nineteenth-century kilns in rural areas away from Kwangju system are not included in the scientific study.

Science of *Pisaek* Celadon

The production parameters of Koryŏ celadon were lost to modern Korea, and the revival of its art and craft in the latter half of the twentieth century was carried out much in trial-and-error efforts. A systematic analysis study dedicated to bisaek celadon is yet to take place, and its compositional and microstructural characteristics are only understood in general terms worked out for celadon. The bodies of celadon considered bisaek appear to be much whiter than common celadon gray bodies, so that their contents of Fe_2O_3 and TiO_2 are suspected to be lower. However, such a systematic difference has not been yet established.

Microstructural images are various features preserved in a frozen state in the process of densification and vitrification when the firing of the

Ceramics in Korea, Fig. 25 A backscattered electron image (BEI) of a celadon body from Sadangni, Kangjin

Ceramics in Korea, Fig. 27 A backscattered electron image (BEI) of a celadon glaze from Sadangni, Kangjin

Ceramics in Korea, Fig. 26 A backscattered electron image (BEI) of a celadon glaze from Sadangni, Kangjin. The shard was made in Sadangni Ahredangjeon in mid-fourteenth century

ceramic pieces is stopped. A typical microstructural image of a celadon body (Fig. 25) reflects the various features of the raw material itself. The black holes in various sizes are the resultant pores that have become coalesced from innumerable small pores, and the dark-gray minerals are quartz. The matrix is made of two different phases intermixed together, the lighter ones

from the melting of feldspar and the darker from the melting of the clay component.

Glaze images are shown in Figs. 26, 27, and 28. In Fig. 26 is a rare wavelike image of an unusual result called the schlieren effect. When the glaze batch is not mixed sufficiently to become completely uniform in composition, the inhomogeneous state is caught as a wave of light and dark areas. Light areas are richer in elements of higher atomic weights, and the dark areas in elements of lower atomic weights. Such an effect of inhomogeneity would have disappeared if the firing continued further. It is not clear whether such an effect was sought after intentionally or not by the potters, but the resulting microstructural feature scatters light in such a way to bring a translucent character to the celadon glaze. Bubbles of round black images, quartz minerals, and crackled line in the left lower corner also participate in the scattering of lights.

Often found in celadon glazes, especially in inlaid celadon, are images of clustered grains occurring around and underneath bubbles (Figs. 27 and 28). They are remnants of granophytic intergrowth of quartz and feldspar in glaze stone. The feldspar part is melted and incorporated into the matrix, while the quartz grains remain as dark grains. In Fig. 28 a rare rodlike

Ceramics in Korea, Fig. 28 A backscattered electron image (BEI) of a celadon glaze from Sadangni, Kangjin

image of muscovite mineral, which is only partially melted around its surroundings, from which are grown anorthite needles during the cooling period after the firing was stopped is also shown.

Ceramics in Pre-Hispanic North America

Suzanne L. Eckert

Arizona State Museum, University of Arizona,
Tucson, AZ, USA

By its very nature, a synthesis of pre-Hispanic pottery technology in North America must be general in terms of both cultural areas and specific techniques. Although it is my hope to present here a fair representation of current knowledge, it is by no means meant to be a final discussion of the topic. Rather, it is my intention to provide a starting point for individuals interested in considering the multiple dimensions of indigenous pottery production in North America over time and space.

Earliest Pottery Production by Cultural Region

North America can be divided into ten broad cultural areas: Arctic and sub-Arctic, Northwest Coast, West Coast (including Baja California), Plateau, Great Basin, southwest United States, northern Mexico, the Plains, northeast United States, and southeast United States (Fig. 1). With the exception of the Northwest Coast (where only a few clay pipes and figurines have been found; Ross, 1990), all of these regions developed or adopted pottery in the pre-Hispanic era. When and how pottery production began in each region varies. In the western Arctic region (Anderson, 1980, 1984; Dumond, 1982, 1983, 1984, 1987; McCartney, 1984), pottery production appeared slightly after 3,000 years ago in association with the Norton Tradition; ceramic technology may have been introduced into the region from Siberia based on similarities in both technology and design (Zhushchikhovskaya, 1997). At about 1,500 years ago, pottery production is associated with the Thule Tradition in the Arctic; based on a few sites with apparently transitional pottery types, the Thule pottery tradition

may be related to the earlier Norton Tradition (Dumond, 1984; Griffin, 1969–1970). Pottery production began as early as 2,600 years ago in the eastern sub-Arctic region (Bonnichsen, Keenlyside, & Turnmire, 1991; McGhee, 1978; Meggars, 1987; Tuck, 1999); this sub-Arctic technology is assumed to have been introduced into the region from the northeast United States even though there are few similarities in pottery from these two regions (Wright, 1981). By 2,300 years ago, pottery production spread into the central sub-Arctic region.

Ceramic material is found throughout the West Coast region in the form of pipes, figurines, small balls (possibly for use in slings), and baked clay items that may have functioned as cooking stones. The earliest pottery vessel tradition in this region, called Owens Valley brown ware, developed in central California about 500 years ago and then diffused west (Elsasser, 1978; Spier, 1978). Although there are some reports of pottery vessels in the southern coastal area dating to as early as 2,500 years ago, this technology apparently faded out and was not resumed again until about 300 years ago in the San Diego area. Pottery entered the Great Basin Region approximately 1,500 years ago with the development of the Fremont Culture (Aikens & Madsen, 1986, 1986, 1989; Marwitt, 1986; Talbot, 2000). Production techniques were probably introduced into the Great Basin Region from the southwest United States and then disappeared from the region around 1,500 years ago; the reason for this disappearance is not well understood.

Probably the most extensively studied pre-Hispanic pottery in North America comes from the southwest United States. The earliest pottery in this region dates to over 2,300 years ago and is associated with the Pioneer period of the Hohokam culture (Gladwin & Gladwin, 1933; Gumerman & Haury, 1979). At about the same time, and probably related, is the introduction of pottery production in the Mogollon cultural area (Martin, 1979; Rinaldo & Bluhm, 1956). Pottery in other areas of the southwest United States began somewhat later, with production beginning at around 1,300 years ago in both the ancestral Pueblo (Anasazi) and Patayan culture areas. It is

Ceramics in Pre-Hispanic North America,

Fig. 1 Map of North America showing prehispanic cultural regions (drawn by author).

generally assumed that pottery technology in the southwest United States was introduced into the region, possibly more than once, from what is present-day Mexico.

Dates for the introduction of pottery in northern Mexico vary by cultural area, with a better understanding for some areas than others. There is evidence that plain ware pottery was being produced as early as 2,500 years ago in the northeast Sonoran area; however, this tradition is not well understood (Douglas & Quijada, 2004). Along the Northwest Coast, pottery production began around 1,800 years ago with the production of Tiburón Plain, a thin, particularly well-made pottery type. Probably the best understood pottery sequence comes from the area around the site of Paquimé in Chihuahua, where the production of pottery began at least 2,000 years ago (Brand, 1935; Carey, 1931; DiPeso, Rinaldo, & Fenner, 1974). This technology is believed to have moved into the area along with groups moving up from Central Mexico.

Very little pottery is reported for the Plateau region: some cave sites have revealed brown-gray pottery that date from 500 to 1,500 years ago (Roll & Hackenberger, 1998). The earliest pottery on the Plains dates to approximately 2,500 years ago and is associated with different complexes depending on the cultural area. For example, the earliest pottery on the Northern Plains is associated with the Besant complex, while the earliest pottery on the southern Plains is associated with the Plains Woodland complexes to the east of the region. Depending on the area within the Plains, this early pottery shows influence from the northeast United States, the southwest United States, or both.

The oldest pottery in North America comes from Stallings Islands in Georgia (Claffin, 1932) and is believed to date as far back as 3,800 years ago (Sassaman, 1998). Pottery in northwest Florida is believed to be nearly as old, while pottery in Maryland dates to approximately 3,000 years ago (Manson, 1948). In other portions of the

southeast United States, pottery technology was adopted much later: the technology may have arrived as recently as 800 years ago in central Texas (Hughes, 1989). In the northeast United States, pottery vessels replaced soapstone vessels as early as 3,500 years ago in southern portions of the region, marking the transition between the Archaic and Woodland periods. In other areas of the northeast, pottery was adopted somewhat later: the northern portion of the region did not make ceramic vessels until approximately 2,000 years ago.

Pottery Production Techniques

Pottery production was one of the more complex technologies employed in pre-Hispanic North America. Potters took a geological material (clay) and, after preparing, shaping, and firing created a new material (ceramic). Ceramic production techniques throughout time and across North America were fairly consistent. The process of making raw clay into ceramic vessels includes five production steps: preparation of raw materials, building or shaping the clay into desired vessels forms, finishing vessels, decorating vessels, and firing.

Preparation of Raw Materials

The one required material for making ceramic vessels is clay. Clay can be found in numerous geological contexts throughout North America, from sedimentary clays in riverbeds to veins of primary clays near mesa tops. Clay is a complex geological material that has been defined by particle size, depositional context, chemical structure, and mineralogical composition. A basic definition of clay is that it is a fine-grained material formed by decomposition of high-alumina- and high-silica-bearing rocks, normally of igneous origin. Although such a definition may be useful for North American archaeologists attempting to find sources of clay used by pre-Hispanic potters, these potters used a different definition for selecting their material. The most

important property of clay is that, due to its small particle size, it becomes plastic when wet. This plasticity allows some clay to be worked into desired shapes. It is this workability that would have been the defining characteristic of clays for pre-Hispanic potters. Other important characteristics for potters include shrinkage rate and amount during drying, firing behavior, texture, and impurities.

Once clay is collected from its geological source, it needs to be prepared. Preparation varies depending on the quality of the clay and what type of vessel is to be shaped. Natural or raw clays often need to be ground, cleaned, and seasoned. Although we do not know with certainty how these tasks were performed in the pre-Hispanic era, ethnographic and historical evidence concerning Native American potters provide some clues. Although clays may be soaked in water to break them down, many indigenous potters grind dry clay with either a combination of mortar and pestle or *mano* and *metate* (Shepard, 1956). Clay needs to be cleaned to remove any coarse particles that may cause a vessel to crack during drying or firing. Methods of cleaning clay vary widely, depending on the extent and size of impurities, but include handpicking, screening in baskets, and washing in water. There is no evidence that North American potters ever used levigation [freeing from grit] to clean their clays. Wet clay is then often seasoned, or soured, by storing it in a cool location for weeks or months. Seasoning clay increases its workability through bacteria growth and the complete wetting of all clay minerals through absorption.

Temper is the nonplastic material in clay. Depending on the type of temper, it can affect various attributes of the raw clay or the final ceramic product including workability, shrinkage, strength, and porosity. Some clay has naturally occurring temper, such as sand. However, potters are required to add nonplastic material to many raw types of clay before forming their vessels. Among historic and ethnographic potters, temper is added at different times during the preparation process; dry clay and temper material may be mixed during the initial grinding of the materials or ground temper may be added

to wet clay that has already been well cleaned. Pre-Hispanic potters in North America used a wide variety of material as temper. For example, charcoal and bone were both used in the southeast United States (Wallis, 2011), while shell was sometimes used on the Plains (Henning, 2001). Sand, igneous rock, mica, and grog (crushed ceramic sherd) have all been reported from archaeological ceramic materials in the southwest United States, as well as untempered pottery (Eckert, 2008).

Shaping the Clay into Desired Vessel Forms

Once the clay has been prepared, it needs to be shaped into the desired form. In the pre-Hispanic era, the shape of a vessel was most often determined by its function; in other words, ceramic vessels were utilitarian in nature and not purely artistic. Pottery was used for many purposes, including storage, cooking, and food service. Broken pieces of pottery were often reshaped into jewelry, gaming pieces, or spindle whorls used in weaving. Common pre-Hispanic forms across North America include jars, bowls, platters, dippers (or ladles), pipes, figurines, and effigy vessels. Pre-Hispanic potters in North America never used a potter's wheel to shape their vessels; all vessels were hand built (Fig. 2). The two most common shaping techniques were coil-and-scrape and paddle-and-anvil; however, drawing-and-pinching and molding techniques were not uncommon (Figs. 3 and 4).

The coil-and-scrape technique involves rolling the prepared clay into ropes and then forming the vessel by successively coiling these ropes one on top of another. Alternatively, the ropes may be formed into rings that are then placed one on top of another. Vessels may be free-formed or ropes may be coiled within a preexisting vessel to help support the shape of the newly formed vessel. The joints are often smoothed over to hide the coils and strengthen the vessel walls, which are then thinned by scraping the vessel with a tool. The use of the coil-and-scrape method in pre-Hispanic North

Ceramics in Pre-Hispanic North America, Fig. 2 All Pre-Hispanic pottery in North America was hand built (drawn by Joshua Keene).

Ceramics in Pre-Hispanic North America, Fig. 3 Pottery vessel smoothed and thinned using coil-and-scrape method (drawn by Joshua Keene).

America has been reported specifically on the West Coast, in the southwest and the southeast United States, and on the Plateau, and the Plains.

The paddle-and-anvil technique involves the potter's taking a mass of prepared clay and then drawing pieces of the clay upwards into the desired vessel shape. In order to thin the walls of the vessel, the exterior surface is slapped with a paddle against an anvil held against the interior surface. Paddles were normally made out of

Ceramics in Pre-Hispanic North America, Fig. 4 Pottery vessel smoothed and thinned using paddle-and-anvil method (drawn by Joshua Keene).

wood and often wrapped with cord or a textile. Anvils could be made from a variety of materials, including wood, clay, or stone. The use of the paddle-and-anvil technique by pre-Hispanic potters has been reported for southern Canada, the southwest United States, northern Mexico, the southeast United States, portions of California, and on the Plains.

Drawing-and-pinching is probably the simplest way to shape clay. A lump of clay is placed on a surface, or held in one hand, while the other hand is used to form an indent in the center of the lump. The potter then pulls (draws) and squeezes (pinches) the clay with one or both hands, while turning the lump of clay, to shape the clay into the desired vessel form. Further pulling and squeezing helps to hollow out and thin the vessel walls. The amount of pinching versus drawing depends on the size of the desired vessel. Pinching is used primarily to form small vessels that can be held in the hand, while drawing is used primarily to form larger vessels that sit on a surface. Drawing-and-pinching can also be used to create the base of vessels that will be further formed using other shaping techniques. Evidence for the use of drawing-and-pinching in the pre-Hispanic era has been reported from all regions of North America.

Molding can also be used to form a vessel. Vessels are shaped by pressing clay into premade containers of the desired form. The use of

complex, multiple piece molds was not practiced in pre-Hispanic North America, with the possible exception of northern Mexico. Instead, simple shapes such as pottery vessels or woven baskets appear to have been used as molds, especially on the Plains, and in the southeast and southwest United States. As with drawing-and-pinching, molding may have been used to form the base of vessels that would then be completed using either the coil-and-scrap or paddle-and-anvil technique.

Finishing Vessels

Once a vessel has been shaped, at least one surface of the vessel is usually finished. Depending on the finishing technique, a potter may choose to finish a surface, while the clay is still wet and plastic, or may choose to wait until the vessel has been dried and the clay is leather hard. Finishing techniques serve primarily to improve the quality of a vessel's surface by removing irregularities that may have been created during the forming process. The choice of finishing techniques relies on the intended purpose of the vessel, whether or not the potter intends to decorate it and, if so, the decorating technique to be used. Finishing techniques used by potters throughout pre-Hispanic North America included smoothing, slipping, and polishing, although the popularity of any single technique varied by cultural region.

Smoothing entails evening out the surface of a vessel with the palm of the hand or with a tool such as a smooth pebble, the smooth surface of a potsherd, or a corncob. Smoothing a surface can be accomplished while the clay is still wet, in which case it is often done as part of the forming process. Smoothing can also be accomplished once the clay is leather hard; however, the application of water to the surface intended to be smoothed is usually necessary once the vessel is dry. Either way, smoothing serves to level ridges and fill depressions, resulting in an even surface.

Slipping involves the application of watered-down clay to the vessel surface. Often, the clay chosen as a slip is not the same clay chosen for the forming of the vessel. A vessel may be slipped to

enhance its appearance by creating a uniform surface; if a slip is thick enough, it hides the temper and other inclusions in the clay used to form the vessel. A slip may also be applied to make the vessel surface, or portions of the surface, a specific color. Finally, a slip may be added to a surface to prepare the vessel for further decoration. A slip may be applied by dipping the vessel into the slip, by pouring the slip over the vessel, or by washing it onto the vessel with the palm of the hand or a rag. Once a slip is applied to a vessel, the surface of the vessel may be polished.

Polishing a vessel serves to give the surface a fine luster. Among historic and ethnographic potters in North America, polish is usually achieved by vigorously rubbing the vessel surface with a smooth stone (Shepard, 1956). Polishing can be accomplished when the clay is still moist or when it is leather hard. Although the surface of a vessel can be polished with or without a slip, it must be well smoothed before polishing can begin. If the surface is uneven, depressions will not be polished, resulting in dull spots, while ridges or inclusions may be pulled, resulting in drag lines.

Decorating Vessels

Although not affecting the function of a vessel in any way, many pre-Hispanic potters chose to decorate their products. Decorations may have had social, religious, economic, or personal significance to the potter. The numerous styles of decoration employed by potters represent the greatest diversity to be found in pottery production in pre-Hispanic North America but is not to be elaborated upon here. The techniques of decoration, however, were limited to the use of coils, surface texturing, painting, and appliqué.

When vessels are formed using the coil-and-scrape method, potters are faced with the decision to smooth the coils or to leave the coils visible. Smoothing the coils increases the strength of the vessel, while leaving the coils visible increases the surface area of the vessel. This latter

characteristic is desirable in vessels to be used for cooking. If a potter chooses to leave the coils visible, she can decorate the coils with various finger indentations or tooled patterns. She can also vary the width of her coils. This technique of decorating a vessel with the coils was well established in the southwest United States, where the corrugated brown wares of the Mogollon culture were some of the finest vessels made in pre-Hispanic North America (Rinaldo & Bluhm, 1956).

The smoothed surface of a vessel can be decorated with various types of texturing. Pieces of textiles, carved wood, or other textured tools can be used to decorate wet clay through stamping, as was common on decorated pottery produced in the Arctic region (Dumond, 1982). On the Plains and in the northeast United States, many vessels were decorated by the impressions left on the exterior surface of the vessel from the paddle used to form them. Paddles were wrapped in cord, netting, or different textiles to create different surface designs on the vessels. Throughout North America, potters gouged, scored, grooved, carved, and incised various designs on their vessels using their fingers or sharps tools. Depending on place and time, these various designs were created when the vessel was still wet, when it was dried to leather hard and, in some instances, once it had been fired.

Painting a vessel requires the application of a pigment to create a design (Fig. 5). Paint can be applied with a finger, with a soft tool such as animal hair, or with a hard tool such as a smoothed piece of bone. Paint can be applied before firing, during the leather-hard stage of production, or after a vessel is fired. In some ethnographic instances, paint is applied after the first firing, and then the vessel is fired a second time to bind the paint to the surface (Fewkes, 1944). Two common types of paints were used throughout pre-Hispanic North America: carbon paint, which was made from organic material, and mineral paint, which was made from nonorganic material. Carbon paint was only applied if a reducing atmosphere was used during firing; in an oxidizing atmosphere, the carbon would have burned away. Further, in the

Ceramics in Pre-Hispanic North America,

Fig. 5 Paint can be applied in a variety of ways, including using a soft brush made of animal hair or plant fibers (drawn by Joshua Keene).

southwest United States, the technology to create glaze paint was developed.

Appliqué involves attaching pieces of clay to a vessel as decoration; unlike the decorative techniques described above, appliqué results in a three-dimensional effect. Throughout pre-Hispanic North America, appliqué was never a primary decorative technique; however, its use has been reported from archaeological context in most cultural regions. The appliqué was often shaped into animal or human forms but was sometimes added simply as trim. In some instances, the appliqué is painted with details, such as eyes or ears.

Firing

Once a vessel has been formed, decorated, and dried to the leather-hard stage, it is fired. It is during firing that the clay material undergoes the chemical change of vitrification (the point at which a pot loses its porosity during firing) and becomes ceramic material. Ceramic material is harder and more brittle than clay, it is often more porous, and it does not become plastic with the addition of water. Although the use of a formal kiln was rare in pre-Hispanic North America, potters still had the same concerns when firing their products as modern potters do: retention of heat, control of draft, and control of atmosphere.

Retention of heat is important because if a vessel is not fired at a high enough temperature for a long enough period of time, the clay does

not vitrify and become ceramic material. Specific temperatures and length of firing depends upon the properties of individual clays. The most common “kiln” in pre-Hispanic North America was the pit kiln (Fig. 6). Potters would have dug a pit into the ground; a fire would have been built into the pit and the vessels placed upon the charcoal from this fire, with further charcoal being placed around and on top of the vessels. Alternatively, the vessels may have been placed within an unfired pit, and then charcoal would have been stacked around the vessels. Although various types of fuel may have been used – including hard wood, coal, and dung – the main requirement of the fuel was that it smoldered. Pottery may also have been fired above ground, with fuel simply being placed under and around the vessels.

It is important to control air drafts to insure even firing and to avoid surface discolorations that are the result of soot coming into contact with the vessels. Although it is easier to control drafts in formal kilns, pre-Hispanic potters using pit kilns or firing above ground had a number of options. If the fuel and vessels were placed appropriately within a pit kiln or above ground, an updraft could have been created that would allow for more even firing, avoid the problem of sooting, and help control the firing atmosphere. To avoid a cross draft, potters could have fired their vessels in areas that were sheltered from the wind or in seasons that were particularly calm.

Pre-Hispanic potters also needed to control the firing atmosphere within their informal kilns;

Ceramics in Pre-Hispanic North America,**Fig. 6** Example of an open pit kiln.

specifically, they needed to worry about the amount of oxygen that entered into the firing atmosphere. They needed to create an oxidizing atmosphere that was sufficiently hot enough for a long enough period of time to completely burn out all organic material. If organic material remains in a vessel during the vitrification process, the vessel surface may bloat and potentially break. Controlling the amount of air in the firing atmosphere for a long enough period of time requires a well-controlled draft as well as the possible need to add fuel. Alternatively, some pre-Hispanic potters fired their vessels in a reducing atmosphere, one in which no oxygen entered the kiln. This is a much more difficult firing atmosphere to obtain in pit kilns, as the fuel must smolder long enough and hot enough for the clay to vitrify into ceramic material, but at the same time no air can be allowed to enter into the system. A reducing atmosphere, although not as hot as an oxidizing atmosphere, allowed for the creation of specific decorative affects including the use of carbon paints and the creation of white slips.

During the firing process, a potter may have chosen to smudge her vessels. Smudging is the process of blackening the surface of a vessel through the deposition of soot. In other words, rather than avoid the discoloration of sooting, some potters appear to have chosen to do this

intentionally. By bringing the vessel surface into contact with the smoldering fuel, and keeping the vessels in a reducing atmosphere, carbon penetrates into the pores of the vessel and turns it permanently black. Potters of the Mogollon culture of the southwest United States developed particularly fine smudged wares, with the entire interior surfaces of their vessels being a dark, even, glossy black.

Although the timing of the adoption of pottery production varies by region, the knowledge of how to produce pottery throughout North America appears to have been gained through diffusion rather than being independently developed. Vessels throughout the continent were hand built, often through either the coil-and-scrape or paddle-and-anvil technique. Once a vessel was formed, decisions on how to finish and decorate a vessel were limited to a handful of techniques. Firing methods were simple, never proceeding beyond pits or simple kilns. Overall, despite the apparent diversity of pottery types that were produced across pre-Hispanic North America, the methods used to produce these vessels were relatively homogenous.

and Vietnam testify that trade contacts between India and Southeast Asia were established by the last century BCE.

Ban Chiang, Udon Thani Province, North-eastern Thailand, is a representative, prehistoric site for the region. Excavations of burials conducted between 1974 and 1986 yielded tons of shards. Various forms of vessels with geometric designs painted in red on a buff-colored body were made using the anvil and paddle technique. The site is dated from BCE 3600 to AD 200.

The prehistoric tradition of making indigenous pottery in Southeast Asia continued into the next period. Thousands of shards unearthed at Angkor Borei, Ta Keo Province, southern Cambodia, are typical pottery of the early historic period, particularly the spouted vessel (*kendi*) with a bulbous body and a spout on the side, which is a ubiquitous form at all early sites in Southeast Asia (Fig. 1).

The earliest transitions from low-fired, unglazed to high-fired glazed ware occurred in Cambodia and Myanmar between the eighth and ninth centuries AD.

Ceramics in Southeast Asia

Dawn F. Rooney

The mainland region of Southeast Asia has a rich, indigenous tradition of ancient ceramic production with centers in the modern nations of Cambodia, Lao People's Democratic Republic (Laos), Myanmar (Burma), Thailand, and Vietnam. The main output was ware for domestic and ritualistic use and regional trade. The insular Southeast Asian region (Brunei, East Timor Indonesia, Malaysia, Philippines, Singapore) made only utilitarian earthenware such as cooking and storage vessels for foods and liquids. It did, though, import trade ceramics from the mainland, China, and Japan beginning in the fourteenth century.

By the second millennium BCE inhabitants of early rice-agriculture settlements in Southeast Asia were making similar types of red-slipped, painted, stamped, and cord-marked pottery. Roulette-made ware from India found in Java

Cambodia

Green-glazed roof tiles from temples of the Angkor Period (AD 802–1432) capital of Hariharalaya (now Roluos), built by King Indravarman I (r. AD 877–889), attest that the Khmers were making glazed stoneware by the late ninth century. Their repertoire expanded to include brown-glazed ware in the eleventh century. Ceramic production in Cambodia continued at least until the end of the thirteenth century. Although the Khmer Empire lasted for another 150 years, ceramics have not yet been positively attributed to the later period.

The first discovery of kilns producing Angkor Period ceramics was in the 1970s in Northeastern Thailand on the Khorat Plateau, an area that was part of the Khmer Empire between the eleventh and the thirteenth centuries. Kilns in Cambodia, however, were not confirmed until 1995.

Ceramics in Southeast Asia, Fig. 1 Spouted vessel (*kendi*). Earthenware. Sisophon, Cambodia. ca. AD sixth century

Groslier proposed the first chronology for Khmer ceramics. He analyzed types of glazes on wares found in excavations in the mid-twentieth century at the Angkor Period Royal Palace compound and in a burial at Srah Srang, the royal bath. Brown published a later refinement of Groslier's chronology (1981).

Two extensive kiln sites have been identified in Buri Ram Province – Ban ("village") Kruat and Ban Baranae. The oval-shape, crossdraft kilns were built of clay slabs with two chambers and a chimney. Both made green- and brown-glazed ware.

Over 12 groups of kilns operating during the Angkor Period in Cambodia have been identified in Siem Reap, Banteay Meanchhey, and Kandal provinces. Anlong Thom, on the southern ridge of Phnom ("Mount") Kulen, 25 mile (40 km) northeast of Angkor, produced high-quality, green-glazed stoneware. The main shapes were architectural fixtures (tiles and finials), covered jars, and bowls (Fig. 2).

The iron-rich body of Khmer stoneware is gray with impurities. Larger vessels were coil-built; smaller ones were thrown on a wheel. The glaze was either brown or green with fine-line cracks. Flaking of the glaze is a common defect. Decoration is always minimal and consists of repetitive geometric patterns encircling the neck, shoulder, or body (Fig. 3).

Ceramics in Southeast Asia, Fig. 2 Green-glazed roof tile. $L = 7.5$ in. (19 cm). Khmer. Tenth century

Some Khmer forms, uncommon in other ceramic traditions of Southeast Asia, may have metal prototypes. Examples are:

- A green-glazed cylindrical covered jar and a bowl with slightly flaring walls and unglazed firing scars around the lower body
- A brown-glazed flattened globular pot with a broad shoulder, a flat base, and a narrow mouth with a rolled rim
- A footed jar with a round body, a flat shoulder, tubular neck, flaring mouth with a flange, and a pedestal base
- Small pots with animal-shape (birds, elephants, rabbits) appendages (Fig. 4)

Laos

Excavations conducted at Sisattanak, near the modern capital of Vientiane in Lao People's Democratic Republic (Laos), in 1970 and 1989 identified a kiln site that operated between the fifteenth and seventeenth centuries based on

Ceramics in Southeast Asia, Fig. 3 Brown-glazed storage jar. *Ht* = 26 in. (66 cm). Khmer. Twelfth century

radiocarbon dating of associated finds. Quantities of unglazed and brown-glazed stoneware shards and wasters were spread over a wide area. The shapes are utilitarian and include bowls, dishes, jars, and pipes (Fig. 5).

Myanmar (Burma)

Architectural plaques and tiles (unglazed and glazed) were used on temples at Bagan (formerly Pagan) in the eleventh century. Geometric tiles are square, round or octagonal and decorated with applied lotus leaves or a lozenge with a blue-green glaze and yellow and white accents. Pictorial plaques portray episodes from the Buddha's former lives (Fig. 6).

Myanmar archaeologists recently discovered hundreds of ancient kilns in Twante district,

Ceramics in Southeast Asia, Fig. 4 Brown-glazed footed jar. *H* = 16 in. (40.6 cm). Khmer. Late eleventh century

Ceramics in Southeast Asia, Fig. 5 Unglazed pipe. Stoneware. *L* = 3.5 in. (8.9 cm). Laotian. Seventeenth Century

approximately 11 mile southwest of the capital, Yangon (formerly Rangoon). They produced only celadon and probably operated between the fifteenth and seventeenth centuries. Previously

Ceramics in Southeast Asia, Fig. 6 Glazed tiles at Naga-yon temple. Bagan, Myanmar. Eleventh Century

Ceramics in Southeast Asia, Fig. 7 Excavated kiln at Twante, Myanmar. Fifteenth to seventeenth centuries

unidentifiable celadon found in burial sites in Indonesia, the Philippines, and Tak and Om Koi are now attributed to Myanmar.

Two kilns were excavated in 1999. The characteristics are (1) oval-shape, (2) crossdraft, and (3) built of clay slabs on a slope with two chambers separated by a low wall and a chimney. An unusual feature of the Twante kilns is the remains of columns in the firing chamber, which were probably used to support a dome-shaped cover. The kiln dimensions are 39×16 ft (11.9×4.9 m). Tubular, clay supports were used to stack the ware. The body contains quartz, other silica, and a high concentration of iron. The characteristics after firing in a reducing atmosphere to a stoneware temperature are: a nonporous body and a wood-ash glaze with iron that produced a transparent, green color. Pooling of the glaze is common. Forms are medium-sized vessels that

were hand-built or thrown on a potter's wheel. Typical shapes are simple bowls, dishes, and plates with minimal geometric decoration (Figs. 7 and 8).

Other known kiln sites in Myanmar include: Lagunbyee, a former Mon center, southwest of Bago (formerly Pegu) where remains of a brick, crossdraft kiln were discovered in 1987 and excavated in 1998–1999; the kiln is 120×70 ft (36.6×21.3 m) and provisionally dated between the eleventh and the thirteenth centuries. Ten kilns and firing supports have been discovered at Myaung-Mya, west of Yangon, near Bassein.

Although kilns have not been found, it is certain that distinctive earthenware with an orange body and an opaque white, vibrant red, or green glaze was made in Myanmar. A variation is a design painted in green under the white glaze (Fig. 9).

Ceramics in Southeast Asia, Fig. 8 Celadon bowl (shard). Twante, Myanmar. Fifteenth to seventeenth centuries

Ceramics in Southeast Asia, Fig. 9 Green and white earthenware shards. Myanmar. Fourteenth to sixteenth centuries

Thailand (Sawankhalok or Si Satchanalai Ware)

Three sources have enabled recent advances in our knowledge of ancient ceramic production in Thailand: underwater archaeology in the Gulf of Thailand where 130 shipwrecks have been reported; excavations of kilns at Sawankhalok and surveys in satellite areas – Phitsanulok, Suphan Buri, and Sing Buri; and ceramic finds in burials at Tak and Om Koi, western Thailand, near the Myanmar border. The quality of ware from the latter is extremely fine and the wide

range includes ceramics from China, Vietnam, Thailand, Cambodia, and Myanmar.

Glazed architectural fixtures were made in the late thirteenth century for the temples of the burgeoning Kingdom of Sukhothai in north-central Thailand (279 mile (449 km) north of the modern capital of Bangkok). As the kingdom expanded, a second city developed at Si Satchanalai, 43 mile (69 km) north of Sukhothai, where kilns producing glazed ceramics were also set up. In the middle of the fourteenth century when Sukhothai became vassalage of the southern Kingdom of Ayutthaya, 49 mile (79 km)

Ceramics in Southeast Asia, Fig. 10 Excavated kiln at Ban Ko Noi. Sawankhalok, Thailand. Fourteenth to fifteenth centuries

inland from the Gulf of Thailand the place name “Si Satchanalai” was changed to “Sawankhalok.” Today, either name is acceptable when referring to the kiln site and the wares. The kilns continued to operate at least through the sixteenth century despite the shift in power.

The dates of operation for the two ceramic centers are not conclusively known. Evidence from shipwrecks carrying ceramics found in the Gulf of Thailand reverses a previously held theory and confirms that the Sukhothai kilns began production later than those at Sawankhalok. During the peak period for the export of ceramics from north-central Thailand (fifteenth and early sixteenth centuries) an estimated 1,000 kilns were operating. Changes in social, economic, and political circumstances of the kingdom most likely impacted on the kilns, causing a gradual decline in ceramic production.

Some 800 kilns have been discovered in the modern village of Ban Ko Noi, 4 mile north of the old city wall on the banks of the Yom River. Ban Pa Yang, a smaller kiln site in the area, produced architectural fixtures, human and animal figures, and brown- and white-glazed trade ware.

Kiln technology at Sawankhalok evolved from a simple bank kiln for firing unglazed, low-fired ware to one constructed of clay slabs that was more sustainable and could hold larger vessels. Finally there was a crossdraft kiln built of prefired bricks. A typical kiln of the latter type is oval shape, crossdraft with a sloping chamber for the wares in the center, a recessed fire-box at one end, and a round chimney at the other. A typical kiln

was 29×11 ft (8.8×3.4 m). For firing, a fixative was applied to the base of a vessel, which was then placed on top of a tubular clay support that was sunk into the sandy floor of the kiln. A black ring on the unglazed base resulted from the fixative of the vessel after firing (Figs. 10 and 11).

Green-Glazed Ware (Celadon)

Sawankhalok celadon is the most widely known product of the ancient Thai kilns. An iron-rich glaze was mixed with ash and fired in a reducing atmosphere. The thick, translucent glaze varies in color from a sea green to olive. Motifs incised in the center of plates and bowls, around the cavetto (a hollow or concave molding in the form of a quadrant) and rim, and on the exterior, drew inspiration from the regional flora, such as lotus and peony. Primary shapes are plates, bowls, bottles, kendis, and jarlets (a small, squat, rounded, or square jar with a small mouth) (Fig. 12).

Brown and White Ware

Sawankhalok kilns produced two other monochrome glazes – brown and white. A typical brown-glazed form is a jar with a tall body, a thick-rolled mouth rim and two handles. A combination of the two glazes on a single piece was a specialty of the export ware made at the Ban Pa Yang kilns (Fig. 13).

Exceptionally large water jars were also made (Fig. 14).

Architectural fixtures, such as tiles, were usually white-glazed (Fig. 15).

Ceramics in Southeast

Asia, Fig. 11 Tubular support for celadon bowl; scar after firing. Sawankhalok, Thailand. Fifteenth century

Ceramics in Southeast Asia, Fig. 12 Celadon plate. Diameter = 11 in. (28 cm). Sawankhalok. Fifteenth century

Quantities of figures (animal and human) were made at Tukatha (Ban Pa Yang kiln site) for the religious and cult needs of the native inhabitants (Fig. 16).

Iron-Decorated Ware

A design was painted on the body with iron oxide; then a transparent clear glaze applied over it. Sometimes a slip was put on the body for a lighter color which created more contrast between the design and the background. Forms include plates, bowls, bottles, kendis, and architectural fixtures. A particular type of round covered box was produced prolifically for export.

Ceramics in Southeast Asia, Fig. 13 Brown-glazed jar. $H = 5$ in. (13 cm). Sawankhalok. Fifteenth century

The body and cover of the box form a continuous line with modeled knob on the cover that is shaped like a lotus bud or in the form of a fruit stem (Fig. 17).

Ceramics in Southeast Asia, Fig. 17 Underglaze glaze painted box with cover. Diameter = 4 in. (10 cm). Sawankhalok. Fifteenth to sixteenth centuries

Thailand (Sukhothai Ware)

Two clusters of over 50 kilns have been identified at Sukhothai – one near Wat (“temple”) Prah Phai Luang and another north of the city wall. The kiln

Ceramics in Southeast Asia, Fig. 18 Disc firing support. Diameter = 4 in. (10 cm). Sukhothai. Fifteenth century

Ceramics in Southeast Asia, Fig. 19 Painted shard. Sukhothai. Fifteenth century

shape and construction are essentially the same as those at Sawankhalok except the Sukhothai kiln is narrower. The average dimensions are 29×8 ft. Plates and bowls were stacked for firing by placing one on top of the other separated by a disc-shaped clay support with spurs (usually five). A distinctive feature in the center of Sukhothai plates and bowls is five circular scars resulting from separating the disc after firing (Fig. 18).

Sukhothai kilns produced two types of ceramics – painted ware and a white-glazed ware. To achieve the former, a slip was applied to a dark body; next, a design was painted using iron oxide; then a thin, transparent glaze was applied. After firing, the texture of the gray body was coarse with visible white flecks of quartz; the color of the iron pigment varied from gray to olive, brown or black; and the glaze is often opaque, or milky in appearance with fine-line crazing and pin holes. A painted fish plate (average diameter = 10 in. (25 cm)) is characteristic of the Sukhothai kilns. The central motif is a single fish, painted in profile, and encircled by one or more rings. Other designs on plates, bowls, and a few bottles such as a single stemmed flower surrounded by leaves and a solar whorl and architectural forms were made at Sukhothai (Fig. 19).

Thailand (Suphan Buri Ware)

A complex of kilns at Ban Bang Pun in Suphan Buri Province, northwest of Ayutthaya, was discovered in the 1980s. The main output was unglazed stoneware footed jars, which were previously attributed to Sawankhalok or Sukhothai. Distinctive, repetitive bands of a leaf motif were stamped around the base of the neck and outer shoulder. The crossdraft, clay kilns were of a similar design to those at Kalong in northern Thailand.

Thailand (Phitsanulok and Nakorn Thai Ware)

Phitsanulok, a small state east of Sukhothai and controlled by the Sukhothai Kingdom in the thirteenth century, became a provincial capital of the Ayutthaya Kingdom in the fifteenth century. Excavations in 1984 at Ban Tao Hai (“village of the jar kilns”) on the eastern bank of the Nan River, 2.5 mile (4 km) north of the modern town of Phitsanulok, revealed two brick, crossdraft kilns of the type developed at Ban Ko Noi with another estimated 40 kilns in the area. A typical jar is baluster-shaped with a flaring mouth and applied decoration. The kiln structure and the output suggest the site operated in the late fourteenth or early fifteenth century.

Ceramics in Southeast Asia, Fig. 20 Excavated kiln at Sankampaeng. Northern Thailand. Mid-fourteenth to mid-sixteenth centuries

The identification of six kilns at Nakorn Thai, east of Phitsanuloke, indicates that it was also a production center for stoneware jars with dates of operation the same as the Phitsanulok kilns.

Thailand (Northern Thai Ware)

Lan Na, founded by King Mengrai in 1292, with a capital at Chiang Mai in Northern Thailand, was an extensive ceramic center making glazed stoneware for domestic and ritualistic needs between the mid-fourteenth and the mid-sixteenth centuries.

The northern kilns were dug from river banks, or made with clay slabs in-ground, or brick-constructed above ground. General characteristics are: small size, simple construction, and crossdraft with two chambers and a chimney. Plates, dishes, and bowls were stacked in the kilns lip to lip and base to base.

Kalong

Over 200 kilns are mid-way between Chiang Mai and Chiang Rai near the valley of the Lao River. Kalong kilns produced ware painted with iron oxide under the glaze in the style of those from north-central Thailand but with more flamboyant motifs executed with broader brush strokes. Dishes with an abstract leaf and flower design are typical. The Kalong kilns also made a fine, thinly potted ware covered with a soft rain-cloud

gray glaze. Vases, bowls, bottles, and dishes comprise this group.

Sankampaeng, Phayao, Nan

Eighty-three kilns are located by the Ping River valley, approximately 15 mile (24 km) east of Chiang Mai. Average dimensions of a kiln are 10 × 4 ft (3 × 1.2 m). Plates and dishes (either painted or brown-glazed) with a central medallion of two fish are typical Sankampaeng ware. Celadon, painted ware, and two-color jars were also common (Figs. 20 and 21).

Kilns were reported at Phayao, in Cham Pawai district, near the remains of an ancient walled city, in the 1950s. The site is unexcavated but shards of celadon, brown-glaze, and two-glaze wares have been found. Stamped motifs and incising through a slip are distinctive characteristics of Phayao ware.

An extensive kiln site was found at Nan, western Thailand, in 1982. It produced painted ware (underglaze black) with a milky white glaze that was placed in a sagger (a box of baked fireproof clay used to protect pieces during firing) for protection during firing.

Phan

Twenty-seven brick kilns situated between Chiang Rai and Phayao are of the crossdraft type with the average dimensions of 20 × 11 ft (6 × 3.4 m). The Phan kilns only produced celadon. It is more carefully potted and more finely

Ceramics in Southeast Asia, Fig. 21 Brown-glazed plate. Diameter = 9 in. (23 cm). Sankampaeng, Northern Thailand. Mid-fourteenth to mid-sixteenth centuries

finished than other northern wares. The shapes include plates, bowls, jars, oil lamps, miniatures, elephants, and kendis. The sophistication and the narrow range of these wares suggest a slightly later date, perhaps from the mid-fifteenth to the mid-sixteenth century.

Thailand (Lamphun (Haripunjaya) Ware)

Although no kilns have been found, shards litter the area of Lamphun, the old Haripunjaya kingdom, and similar ones were found at Tak and Om Koi. These finds suggest a mid-fourteenth to mid-sixteenth century date. The finely textured body is either orange or brownish black. A typical form is a thinly potted, globular, long-necked bottle with a flat base, inlaid with slip, and either intricate white or black geometric motifs on the neck and body.

Thailand (Sing Buri or Maenam Noi Ware)

Excavations conducted in 1987 in Bang Rachan district of Sing Buri Province at the Tao Maenam Noi kiln site established the provenance of a class of brown-glazed storage jars previously believed

Ceramics in Southeast Asia, Fig. 22 Brown-glazed jar. $H = 18$ in. (45.7 cm). Sing Buri, Thailand. Late sixteenth to early seventeenth centuries

to be Sukhothai. As the kilns are located near a temple, the ware is popularly called Wat (“temple”) Phra Prang Pottery. The oval-shape, crossdraft, brick kiln measures 44 ft (13.4 m) long and is the largest one found so far in Thailand. Both unglazed and glazed ware was made, mostly storage jars but also unglazed kendis. A typical jar is heavily potted, with an ovoid body and a narrow neck with a rolled lip and partially covered with a brown glaze. These jars have been found in the cargo of a number of shipwrecks in the Gulf of Thailand dating to the late sixteenth or early seventeenth centuries (Fig. 22).

Vietnam

The glazed ceramic tradition of Vietnam is unlike any other in Southeast Asia as it was strongly

Ceramics in Southeast Asia, Fig. 23 Green-glazed lime pot. $H = 7$ in. (18 cm). Vietnamese. Fifteenth to sixteenth centuries

influenced throughout history by China, both technically and stylistically. Its development, forms, and motifs, therefore, are parallel approximately that of Chinese ceramics. Extensive excavations of burial grounds in the early twentieth century in Thanh-hoa Province, northern Vietnam, yielded quantities of ceramics dated between the tenth and the thirteenth or fourteenth centuries. Kilns near the modern city of Hanoi, the site of capitals of the Ly (AD 1009–1225) and the Tran (1225–1400) dynasties, were most likely the source of the Thanh-hoa ware. Vietnamese ceramics entered the export market in the fourteenth or early fifteenth century with painted ware in both underglaze blue and black. Despite the Chinese influence, some forms are distinctively Vietnamese. A storage container for lime to use for betel chewing is an example. The squat form has a small opening on the shoulder, a pedestal foot, and a “basket-like” handle with

elaborate decoration. Ritualistic ceramics made in the late sixteenth or seventeenth century at kilns near Hanoi are distinguished by large altar vases and incense burners (Fig. 23).

Ceramics in the West Indies

Todd Ahlman

Center for Archaeological Studies, Texas State University, San Marcos, TX, USA

The West Indies are a series of 28 island nations and over 7,000 islands in the Caribbean Sea and Atlantic Ocean between North and South America (Fig. 1). The islands include the Greater Antilles, which are the more northern and larger islands of Cuba, Hispaniola, Jamaica, and Puerto Rico, and the Lesser Antilles, which are the islands from the United States Virgin Islands south to Trinidad. The West Indies also include the Bahamas, Aruba, Bonaire, and Curacao. The islands vary in size, topography, and proximity to one another, which has had an influence on pre-historic and historic settlement, subsistence, and material culture. Pre-Columbian pottery in the West Indies is very diverse due to the geographical breadth of the region and influences from South and Central America and possibly North America. After European contact, the many islands were colonized by the Spanish, British, French, and Dutch, and the Amerindian populations in the West Indies were quickly decimated on most islands. A plantation economy was soon in place where enslaved Africans worked the sugar, tobacco, spice, coffee, cotton, and indigo plantations.

The West Indies were first settled from South America around 7,000 years ago and from

Ceramics in the West Indies, Fig. 1 Location of West Indies with subregions and islands mentioned in text identified

Central America about 6,000 years ago. The first settlers of the West Indies engaged in marine and terrestrial subsistence with material culture of ground stone, coral, and shell tools. The paucity of quality cryptocrystalline stone meant that stone tools were not widely used. Pottery first appears in the West Indies as early as 800 BC during the Saladoid period. The Saladoid takes its name from the type site in the Orinoco valley of Venezuela where it is thought the people who brought ceramics to the West Indies originated. The earliest known Saladoid sites are in Montserrat, St. Martin, Puerto Rico, and the Virgin Islands.

The Saladoid period is marked by horticulture, hunting and fishing, permanent villages, and pottery. The presence of griddles indicates the cultivation of manioc roots as well as other root and vegetable crops. Pottery is the defining feature of the Saladoid period and includes a variety of

plain as well as highly decorated pieces. Early Saladoid pottery is marked by white-on-red painted decorations, modeled-incised adornos, and zone-incised cross-hatching (Fig. 2). After AD 400, Saladoid pottery becomes thicker and heavier and has polychrome decorations with white, red, black, and orange painting, modeled-incised zoomorphic and anthropomorphic adornos [ornamentation on the rims or handles of ceramic pieces] (Fig. 3), incised motifs (Fig. 4), and some zone-incised crosshatched decorations. Barrancoid pottery developed around AD 650 in the southern West Indies and occurred concurrently with Saladoid pottery with influences from South America. Barrancoid pottery has modeled-incised handles, and anthropomorphic and zoomorphic hand, feet, and face adornos.

At the same time as the Saladoid, Huecoid ceramics developed in the northern West Indies

around 800 BC and lasted through AD 200. Researchers believe this pottery has influences from Central America. These ceramics are decorated with curvilinear-incised zones with punctuates and cross-hatching. Huecoid ceramics were not painted, but some included white or red paint or slip rubbed into the incised or hatched patterning. Some pottery was adorned with zoomorphic adornos (Fig. 5) and/or shaped into aquatic animal forms.

Ceramics in the West Indies, Fig. 2 Zone-incised cross-hatching decoration on bowl (Drawn by Eric Carlson after Fig. 61 in Hardy, Meredith Devereaux, Saladoid Economy and Complexity on the Arawakan Frontier. Unpublished Ph.D. dissertation, Department of Anthropology, Florida State University. 2008)

The Casimiroid is a preceramic period that developed independently on Cuba and Hispaniola starting around 4000 BC. Casimiroid pottery developed on Hispaniola during the Courian subperiod between 2630 BC and AD 240 on Hispaniola.

During the post-Saladoid period, a differentiation in pottery series between the Greater Antilles and northern West Indies and the Lesser Antilles appears. In the Greater Antilles, the Ostinoïd series developed from the Saladoid or Casimiroid periods in Cuba, Hispaniola, Jamaica, Puerto Rico, and the Bahamas around AD 600 and continued until AD 1500. The Ostinoïd series is further broken into regional and temporal variations based on pottery decoration and forms with variants often occurring simultaneously on the same island. The Troumassoid series developed in the Lesser Antilles during the same period and is broken into temporal subseries.

In the Greater Antilles, the Elena Ostinoïd dates from around AD 600 to AD 1200 and occurs in eastern Puerto Rico and the Virgin Islands. This pottery series is marked by a reduction in decorative elaboration and overall craftsmanship from the earlier Saladoid but appears to be better suited for utilitarian uses. During the first half of the period, red-painted and plain varieties dominate with smaller numbers of black, negative, and smudged decorations. Bio-morphic modeled, strap, lug, and tubular handles are also found. The second half of the period shows a return to modeled and incised

Ceramics in the West Indies, Fig. 5 Huecoid screech owl adorno (Drawn by Eric Carlson after Fig. 24 in Waldron, Lawrence. *Geographic Distributions of Zoomorphic Motifs in Saladoid Ceramics*. *Caribbean Connections*. 2011. http://fieldresearchcentre.weebly.com/uploads/1/8/0/7/18079819/waldron_2011.pdf)

decorations, zoomorphic adornment, and an almost absence of painted or slipped decorations.

The Ostionan Ostionoid dates from AD 600–1200 and has been found in western Puerto Rico as well as Jamaica, Hispaniola, and Cuba. There is also a simplification in pottery decoration and styles during the Ostionan, but many Saladoid variations are retained. Red-painted or

slipped varieties survive along with looped handles and zone painting. Island variation exists with red-, pink-, or lilac-colored painting, incising, and zoomorphic adornments.

The Meillacan Ostionoid was first defined in Hispaniola and is found in Cuba, Jamaica, and parts of the Bahamas and dates from AD 600–1500. There is debate as to whether the Meillacan Ostionoid developed in place from the Casimiroid, developed out of South American influences, or borrowed from the Ostionan Ostionoid, but there do not seem to be many Saladoid influences. The pottery almost is devoid of painting and is generally characterized by rectilinear incising that forms hatching and cross-hatching designs along with punctuates and appliques. Handles are generally straps with geometric or zoomorphic decorations.

The Chican Ostionoid dates from AD 800–1500 but is most common from AD 1200–1500. This pottery is found in the Virgin Islands, Puerto Rico, eastern and southern Hispaniola, eastern Cuba, the Bahamas, and the northern Lesser Antilles. Chican Ostionoid pottery is primarily characterized by bowls with incised shoulders with circles, triangles, parallel dashes, and lines. Painted pottery is almost absent from this series but is found at some sites. Handles include biomorphic, modeled head lugs, and adornos.

The Palmettan Ostionoid is found in the Bahamas and Turks and Caicos islands and dates from AD 600–1500. This pottery series was previously

Ceramics in the West Indies, Fig. 6 British-made blue transfer printed pearlware that dates from 1780 to 1820 (Photo by author)

thought to be unrelated to other West Indian ceramics but is now thought to be related to the Chicano Ostinoid and Meillacan Ostinoid based on similar decorations. The Palmettan Ostinoid has been divided into subseries such as Abaco Redware, Crooked Island ware, and Palmetto ware that does not necessarily correlate with specific geographical areas. There is temporal variation in these subseries with the Abaco and Crooked Island ware occurring before the Palmetto ware.

In the Lesser Antilles, the Troumassoid ceramic series follows the Saladoid series and is divided into two temporal periods: Troumassan and Suazan Troumassoid. The Troumassan Troumassoid immediately follows the Saladoid period and dates from AD 600–1000. This subseries carries forward many Saladoid characteristics, but over time, there is a trend in decreasing decorative and vessel-form complexity. In the northern Leeward Islands, the Troumassan pottery has bicolor and polychrome painting with broad-lined and curvilinear incisions. In the

Windward Islands, the Troumassan Troumassoid is characterized by decreasing complexity in decoration with red, black, and white paints and curvilinear-incised lines dominating. There are many similarities to pottery from South America, including cotton spindle whorls suggestive of cotton cultivation and trade.

The Suazan Troumassoid subseries dates to AD 1000–1500 marks the end of the pre-Columbian pottery production in the Lesser Antilles. This period continues the overall post-Saladoid trend in pottery simplification with thicker walls, rough or scraped surfaces, and finger-indented rims. Utilitarian wares dominate assemblages, but finer wares do appear in smaller amounts and include polychrome and red painting, curvilinear and linear incising, and modeled anthropomorphic and zoomorphic adornments. Utilitarian vessel forms include griddle, incense burners, spindle whorls, and pestles.

The contact period between Amerindians and Europeans shows a continuation of the Ostinoid and Troumassoid series characteristics as well as

Ceramics in the West Indies, Fig. 7 Afro-Caribbean ware bowl from St. Kitts (Photo by author)

a melding of these traditions, influences from South America, and evidence of interactions with Europeans. For instance, the Cayoid pottery series in the central and southern Lesser Antilles dates from AD 1550–1650 and was thought to have formed out of the preceding Suazan Troumassoid. Recent research, however, has shown similarities to Carib pottery from the Guianas, and researchers believe the pottery has direct ties to South America. This idea blends well with Island Carib traditions that state Carib men came from South America and were in regular contact with Amerindian groups throughout the West Indies and South America. Cayoid pottery has decorations with similarities to the Polychrome Tradition of Amazonian vessel forms with decorative motifs related to the Chicoid Ostinoid of the Greater Antilles, and rough-surfaced griddle and bowls like those from the Suazan Troumassoid. A few Cayoid pottery shards found on St. Vincent have European beads embedded in the rims.

Ceramics during the historic period include the full gamut of European wares typical of the colonial period (Fig. 6). In general, the ceramics of each island reflects the national identity of the European colonizing nation. For instance, on

Ceramics in the West Indies, Fig. 8 Afro-Caribbean ware bowl from St. Kitts (Photo by author)

islands like Montserrat and Nevis, the ceramics are distinctively British, but on St. Eustatius, a Dutch island that served as a major port and shopping center, the ceramics are much more diverse and include Dutch, British, French, and Spanish ceramics.

During the historic period, enslaved and freed Africans made and traded pottery called by

Ceramics in the West Indies, Fig. 9 Afro-Caribbean ware rims with iron oxide slip (Photo by author)

archaeologists Afro-Caribbean ware (Figs. 7, 8, and 9). Afro-Caribbean ware is a handmade, low-fired earthenware made by enslaved and freed Africans throughout the West Indies. First identified on Barbados in the 1960s, this pottery has become one of the most studied historic material types on the West Indies because it represents a direct connection to the slaves who made and used the pottery. Analyses have included macroscopic examination of paste characteristics, petrographic study of inclusions and construction methods, and INAA of the chemical composition. These analyses have identified a vibrant production history that hit its height during the late eighteenth and early nineteenth centuries. Researchers have examined the trade networks on Jamaica and found that pottery was likely made in certain production centers and radiated out along known travel routes. Within the Lesser Antilles, intransland trade was extremely important, but some researchers have explored the interisland trade of the pottery. Researchers have used instrumental neutron activation analysis to examine the chemical composition of pottery shards to study this trade and found that

numerous compositional groups occur throughout the islands and that some groups occur on more than one island. For instance, shards likely made on Nevis or St. Kitts occur on those islands as well as St. Eustatius and Antigua. Modern day potters continue to make similar pottery on Nevis, St. Lucia, Antigua, Jamaica, and several other islands.

Ceramics in West Africa

Liza Gijanto

St. Mary's College of Maryland, St. Mary's City,
MD, USA

Archaeologists, anthropologists, and art historians have studied ceramics in West Africa. These studies have focused on ceramics as markers of identity, the role of ceramics in ritual practice, and the gendered nature of ceramic production. A range of technical and stylistic ceramic forms have been identified throughout West Africa that can be correlated with different historically known ethnolinguistic groups to varying degrees (Mayor, 2010). A number of long-term regional studies in West Africa are focused on filling the gaps in our knowledge of the origins and development of ceramic traditions in the region utilizing archaeological and ethnographic research. These include the Mandara Archaeological Project in Cameroon, Nigeria, and Ghana (David, 1998) and the Mission Archéologique et Ethnoarchéologique Suisse en Afrique de l'Ouest (MAESAO) in Mali (Gallay, Huyssecom, & Mayor, 1998; Mayor, 2010). Both projects trace changes in ceramic technology and style. However, the numerous similarities between decorative styles and vessel forms make it difficult to delineate potting traditions based solely on aesthetics. In this entry, key aspects of the different ceramics, potting techniques, and traditions are highlighted, recognizing that this is by no means an exhaustive summary. As such, only ceramic vessels and not other objects made from fired clay will be addressed.

Definitions and Characteristics

West African ceramics are classified as low-fired earthenware and are typically some form of hollowware vessel serving a range of purposes. Most ceramics function as cooking, serving, and storage containers for water, medicine, oil, or grain.

Ritual ceramics are also produced and may be similar in shape and design to those used for foodways. In the Gambia, restricted hollowware vessels similar to those used for storage would also serve ritual functions. These vessels would be transformed into juju (a ritual charm or amulet) through burial. Archaeological examples include pots containing stone, animal bone, and botanical remains. Ritual ceramics can also be incorporated into shrines or burials. These ceramics are often similar in form to everyday wares and can be identified by their poorer quality (Norman, 2009, p. 196). There are also specialized forms that are produced in areas of Benin and Ghana.

West African ceramics are less refined than wheel-thrown and kiln-fired wares because of the lower firing heat which in turn makes them more porous. The potter builds the vessel by hand using local clays. Clay extraction is carried out in a number of ways including surface collection, pit extraction, gallery extraction, and underwater collection (Gosselain & Smith, 2005, p. 3). Throughout most of West Africa, the local clay requires processing and tempering agents such as chaff, sand, grog (broken ceramic), or shell to survive the firing process. The vessels are created from the processed clay using a range of shaping techniques including but not limited to coiling, slab, or pound molding, molding over an existing pot (convex-form molding), or molding in a convex form. Many potters utilize a combination of these techniques, shaping the body of the pot in one way and adding the rim manufactured in another. Depending on the ability of the potter, the manufacturing technique may be evident in the final product (Figs. 1 and 2).

Once the pots are shaped and smoothed, they are left to dry until they are leather hard. At this stage, various finishing techniques may be used. Finishing techniques include slips, burnishing, smoothing, or painting the surfaces of the vessel. In addition, decorative elements are often impressed or carved into the exterior of the vessel at this time. The most common decorating technique identified throughout West Africa both archaeologically and ethnographically is rouletting. Camps-Fabrer (1966) classified a range of

Ceramics in West Africa,
Fig. 1 The nineteenth-century ceramic rim and body sherd from Berefet, Gambia, with no visible evidence of coiling

Ceramics in West Africa, Fig. 2 The nineteenth-century ceramic rim and body sherds from Berefet, Gambia, exhibiting evidence of coiling manufacturing

roulette decorations based upon the tool used. These could be applied to the ceramics vessel using a braided cord, cord-wrapped stick, or natural plant material. McIntosh (1995) and Galley (1970) have expanded this list to include a greater range of cord-wrapped designs as well as impressions made using various types of shells. Various patterns have been associated with different regional areas and have demonstrated a temporal variation (Haour et al., 2010, pp. 7–9). However, ethnographic work has demonstrated that technical style (i.e., vessel construction techniques) is more closely tied to ethnic affiliation than decorative motifs (Mayor, 2010, p. 15). This is largely attributed to the fact that it is easier to mimic a design than gain access to technical knowledge which requires a period of apprenticeship. The completed pots are piled together and surrounded by fuel. This is an open-air firing process with the vessel in direct contact with the fuel source which can be wood, straw, or palm leaves depending on what is available in the local environment.

Origins and Ceramic Traditions

Ceramic production in Africa is believed to have originated in the Central and Eastern Sahara as well as the Nile Valley between the late tenth and early ninth millennium BC (Jesse, 2003, pp. 40–42), and the technology expanded from the east, including the modern nation of Sudan. The earliest known West African ceramics were found at Mouche at Ounjougou in Mali. These have been dated to the late tenth millennium BC using C14 and OSL techniques (Huysecom et al., 2009, pp. 906, 907). This places the beginning of ceramic production in sub-Saharan Africa as early as production in the Nile Valley. Three ceramics were recovered dating to this period at Mouche. Vessel form could only be determined from one sherd which is a rounded bowl. A second sherd has an impressed decoration (Huysecom et al., 2009 pp. 910). These sherds are clear antecedents to the variety of ceramics manufactured throughout sub-Sahara into the present.

There are distinct differences that have been observed in the archaeological record that persist today between ceramic traditions in the northern Sahel-Sudanic and southern savanna-forest regions. This historical division is first observed in ceramics from Koroukorokalé (Mali) dating between 4240 and 3800 BC. These vessels are described as an offshoot of the northern traditions found in the inland Niger Delta including Djenné-Djeno. It is not until the third millennium AD that distinct ceramic traditions have been identified by archaeologists in Mali that are distinguishable from neighboring areas by both aesthetic and technical style (McIntosh, 1995, pp. 130–215). The phase I ceramics identified at Djenné-Djeno are semi-refined open and closed hollow vessels with a high prevalence of twine impressions and grog-tempered wares (McIntosh, 1995, p. 212). Those from the southern savanna and forest zones are characterized by everted rims and course grog-tempered paste and they are decorated using relief or grooved motifs (Frank, 1998, p. 20).

Production Organization

The primary producers of ceramic vessels in West Africa are overwhelmingly women. Male potters are rare but can be found among the Mossi (Ivory Coast, Burkina Faso, and Nigeria) and Hausa (Nigeria) to name a few examples. While women create ceramic vessels, they are often prohibited from producing other objects from clay. This is seen among the Asante whereby women are not allowed to create pipes or anthropomorphic figures (Rattray, 1927, p. 301). Potters are present in nearly all ethnic groups in the region, with a few exceptions (e.g., the Bozo). In those societies where craft castes are present, potting is restricted to women of particular lineages. They can be members of these lineages either through birth or marriage. For several groups including the Mande, Dogan, Senufo, Mafa, and Dowayo, only the wives of blacksmiths can be potters (Vincentelli, 2004, p. 51). Fulani potters also marry blacksmiths, but they can also be the wives of weavers,

leatherworkers, or woodcarvers (Mayor, 2010, p. 9). For many groups, a potter is viewed as a female blacksmith, and a Dogan legend suggests that pottery originated in the smithy (Barley, 1994, p. 53).

Mande potters in the Kadiolo region of Mali are tied to griot rather than blacksmith lineages. Frank (1993) has convincingly argued that this anomaly to Mande tradition is the result of these women's ancestry as slaves in the region. Precautions are taken in many of these societies to restrict craft production to the proper lineage. For example, the Senufo will not train a potter until after marriage, whereas many Mande women will marry men outside of their village in order to ensure that they are blacksmiths.

In addition to lineage-based restrictions, other taboos surround ceramic manufacture. Much of this is tied to beliefs about the nature of the earth. In many societies, the earth is considered female and a connection is made between various forms of production including potting to fertility and reproduction. These taboos can be specific to a particular vessel that is made, the time when potting can take place or who is able to pot at certain times. Among the Yoruba, red is not worn when near the clay pits because of its association with menstruation. Age restrictions are present in different societies as well. For the Yoruba, post-menopausal women cannot make sieves which are used in grain processing. Kelly and Norman (2006) have noted that production of specific ceramic forms is restricted to different potters in southern Benin. Older Gbe-speaking women in this area control the local industry, and they are the only ones able to produce ritual ceramics. The Bamana presents a further example. For them, girls are not deemed full-fledged potters until they go through an excision ritual. During this, their virginity is checked, and those who do not pass are banned from potting (Herbert, 1993, p. 209).

Ceramic production has declined significantly in West Africa beginning in the mid-twentieth century. This has been correlated to the widespread availability of low-cost metal and enamel

wares. While the production of everyday utilitarian vessels is declining, specialized wares continue to be manufactured. In Benin, the production of ritual vessels continues, though other forms have fallen into decline. An extreme example of this loss of potting traditions is the situation in the Gambia where only a small number of villages have women who continue to produce ceramics (Vincentelli, 2004, pp. 53–54). These include villages in the Foni and Wuuli districts. Regional production is evident in the physical nature of these ceramics despite the fact that the potters are Mande. Both traditions utilize grog temper. The Foni wares are not burnished and have red- to orange-painted decorations. In contrast, those produced in upcountry are highly burnished and have white-painted designs (Fig. 3). The vessels produced by all potters are limited to closed pots, incense burners, large water storage containers, and steamers.

Conclusion and Observations

West African ceramic production is a long-standing practice. As a material class, these are distinguished from imported wares by their coarse texture and lack of glaze. These ceramics were and continue to be a craft or cottage industry rather than being mass produced. Because of the localized production, the ways in which the pots are created as well as decorated at times can signal ethnic affiliations. This correlation has been used to understand past migrations and settlement throughout the region. Ethnographic research has highlighted the engendered nature of production. The majority of West Africans who have in the past and continue to produce ceramic pots are women. The abandonment of ceramic production in different areas of West Africa is primarily the result of cheap and readily available alternatives including metal and plastic wares. Because of this decline, ceramics that are produced today are highly specialized for either domestic or ritual use.

Ceramics: Maya Pottery

Sandra L. López Varela
 Facultad de Filosofía y Letras, Universidad
 Nacional Autónoma de México, Mexico, DF,
 Mexico

A social analysis of pottery investigates how potters translated into clay the social values and representations of people's lives, simultaneously considering how these objects defined their being in the world (Fig. 1). After decades of studying Maya pottery as a chronological marker of site interactions, ceramicists in the Maya region are researching the life histories of pots and potters under new theoretical paradigms and techniques (Jackson, 2009; LeCount, 2010; López Varela & Dore, 2005; Luke, 2012). Maya pottery studies are ready to begin this new journey, after a long history of using a methodological approach known as the type-variety system. Maya pottery is the result of a high level of technological expertise and knowledge. Each pot was made and used for the daily life activities of people we now called “the Maya.”

Analytical Approaches to the Study of Maya Pottery

Since the beginning of the twentieth century, archaeologists have studied pottery mostly to order archaeological remains in time and space so they can interpret past cultures. There are many reasons why pottery became the ideal data to reconstruct culture. Basically, pottery fragments can be arranged in a sequence of formal characteristics and styles called attributes. By determining the location of the pottery type in a stratigraphic column, the archaeologist dates a particular time and is able to produce a ceramic sequence. These goals in archaeological research conformed to cultural relativism, a theoretical and methodological approach established by Franz Boas, concerned with documenting culture-historical sequences and influences (Hodder, 2004, p. 23).

Deriving from these goals, the type-variety system was introduced in 1960, as a systematic procedure to describe Maya pottery (Smith, Willey, & Gifford, 1960). To establish a type, the analyst takes into consideration decorative techniques and vessel form. When the analyst notes differences in ware, decorative techniques, vessel form, design, or temper, a variety of a type is established. The ware describes the paste composition (texture, temper, hardness, porosity, and color) and surface finish. When several types share the same ware, they form a ceramic group. Simultaneously, all of the known attributes are indicative of a particular class of pottery produced during a specific time interval known as the ceramic complex (Sabloff & Smith, 1969, p. 77). By 1965, use of the “system,” as colloquially referred to by its users, had created analytical and methodological problems. These were discussed during the Maya Ceramics Conference, held in Guatemala City (Willey, Adams, & Culbert, 1967). The strengths and weaknesses of the type-variety system, assessed mostly in qualitative terms, continue to be discussed and debated (Adams, 2008; Aimers, 2013; Culbert & Rands, 2007).

In 1969, Sabloff and Smith introduced a format to present the type descriptions of the

Ceramics: Maya Pottery,

Fig. 1 Learning how potters translated into clay the social values and representations of people's lives is a challenge for pottery analysis (Illustration by Sandra L. López Varela)

Seibal pottery, used by archaeologists working in the southwest of the United States (Colton & Hargrave, 1937). For many analysts, the format, later extended in the Seibal monograph (Sabloff, 1975), introduced a comparative framework for understanding pottery network distributions and extended the possibility to recognize new pottery attributes, leading to the establishment of new categories (e.g., Adams, 1971; Kosakowsky, 1987; López Varela, 1989; Smith & Gifford, 1966; Valdez, 1987; Varela Torrecilla, 1998). Each resulting monograph, presenting the description of the pottery and chronology, is to Maya pottery analysis the equivalent of any taxonomy book to biology. The analyst learns the taxa by reading the descriptions of the pottery and looking at the illustrations reported in the monograph.

In the field, the “system” may only be qualified as invaluable to the ceramic analyst, studying hundreds of bagged pottery fragments to answer common questions raised by archaeologists regarding the time framework of every excavated context. The type-variety system is used as a quick and reliable method to compare and date pottery (Smith, 1979). The analyst is able to date any context, “good, fast, and cheap,” with the type-variety system. The type-variety system has become a common artificial language for

Maya ceramicists. The system provides artificial identities necessary for archaeologists to state what something is and what it is not; otherwise, there would be no process of communication to interpret their results. However, to study the richness in form and dexterity in the making of every Maya vessel, multiple approaches are needed. The type-variety system is the essential first step.

Early Uses of Science and Technology in Maya Pottery Studies

After World War II, the North American school of archaeology adopted the scientific method (Binford, 1962). This new way of doing science involved the testing of hypotheses, using technology and rigorous methods, such as statistics, to produce a law, model, or theory adequately accounting for cultural phenomena. Archaeology was concerned with objectivity, systematization, and the need to provide explanations of the observed phenomena.

The search for objectivity raised criticism of the failures of taxonomic systems to appraise the meaning of pottery (e.g., Dunnell, 1971). Krieger (1944, p. 272) suggested objectivity could be reached based on demonstrable historical factors, not only on “the inclinations of the analyst or the niceties of descriptive orderliness.” Most of the debates were trapped in an endless circular

discussion of subjectivity versus objectivity, determining how many conditions are necessary for membership in a class.

In following this scientific trend, quantitative methods to approach the chronological ordering and distribution of pottery were introduced in Maya pottery studies. Statistical methods, such as seriation, were used to learn about the inherent space and time dimensionalities of Maya pottery (Henderson & Beaudry-Corbett, 1993; López Varela, 1989; Vallo, 2002). Seriation is a relative dating technique considering the chronological ordering of a group of artifacts or assemblages, where the most similar ones are placed adjacent to each other in the series. The seriation method, however, is not an objective means for finding the life span of artifacts, as it orders the number of pottery attributes defined by the type-variety system.

Interest in understanding the craft specialization and technology of Maya pottery required the integration of mineralogical analysis (Ford & Rose 1995; Iceland & Goldberg, 1999; Jones, 1986). Archaeologists use petrography to identify rocks in thin sections precisely, aided by a microscope and careful mapping of rock units. Petrography is primarily concerned with the systematic classification and precise identification of rocks in thin sections, aided by a microscope and careful mapping of rock units. Instrumental techniques, mainly INAA (instrumental neutron activation analysis) and XRF (X-ray diffraction), have been used to investigate the provenience and to determine the concentration of trace and major chemical elements in Maya pottery (Rice, 1976).

The use of instrumental techniques implicitly assumes the results provide us with information about Maya pottery production and distribution. Archaeologists have accepted the resulting data, under the strength of “scientific authority,” without being able to interpret the nature of the data adequately or the problems regarding the analytical sensitivity, precision, and accuracy of physical or chemical techniques, including the preferential use of some laboratories (Bishop,

Canouts, Crown, & De Atley, 1990). Customarily, instrumental techniques are giving us information about the provenance of 13 or 19 chemical elements in “pure” form (Kosakowsky, Estrada Belli, & Neff, 1999; Neff, Bove, Robinson, & Arroyo, 1994; Neff, Cogswell, Kosakowsky, Estrada Belli & Bove, 1999). The given set is integrated by some of the most abundant chemical elements on earth. Absent from INAA results is silicium (Si, silicon in English) and aluminum (Al), the main components of silicate minerals and aluminum oxides, constituting the basis of pottery clay.

The limitations in the use of instrumental techniques is not the failure of a particular laboratory and analysts, but, rather, the limitations of solving an archaeological problem. There is a substantial analytical difference between learning about the technology of pottery making and identifying the chemical elements in a pot. Contrary to Neff’s (2005, p. 210) position, if we were to guide these studies from an anthropological perspective, it would matter if we used chemical or mineralogical approaches to source determination or how many chemical elements of the periodic table need to be measured to learn about the making of pottery. When we look through the microscope, we are observing a substance containing no social information. The analyst considers a chemical compound, such as carbonates, as a triangular structure with a carbon at its center and an oxygen atom on each corner, bearing distinctive density or coloration qualities, except social information (Fig. 2). When the archaeologist wants to extract social meaning from what he has observed under the microscope, this corollary is unintelligible to the chemist. Chemical phenomena occupy a realm largely distinct from social phenomena (Latour, Woolgar, & Salk, 1986, p. 23). In opposition, the construction of knowledge in archaeology reads science as culture. Material sciences are mostly applied to provide precise physical and chemical properties from which an object is constituted to learn about culture or human behavior (Jones, 2002, p. 66).

Ceramics: Maya Pottery, Fig. 2 Chemical elements and minerals contain no social information. Carbonates identify as a triangular structure with a carbon at its center and an oxygen atom on each corner, bearing distinctive density or coloration qualities, except social information (Illustration by Sandra L. López Varela)

New Routes for the Use of Science and Technology in Maya Pottery Studies

Instrumental techniques are being used to learn about Maya pottery, as a complex mixture of raw materials often from disparate sources with clay and non-clay minerals mixed together in different forms and varying ways to produce a pottery fabric. These increasingly available studies are using technology to learn about the uses of pottery and the choices potters made to produce a pot. These studies are providing the field of Maya pottery with insightful analytical results (García-Heras et al., 2006; Goodall, Hall, Viel & Fredericks, 2009; Fanjat et al., 2013; López Varela, 2005a; Meanwell, Paris, Cruz Alvarado, & Peraza Lope, 2013).

The Maya region is a vast terrain with varying geologies and topographies providing the raw materials for many different recipes to make pots. These raw materials were washed or levigated (made smooth), and non-plastic temper (to create hardness and elasticity) of certain grain sizes was added or mixed with other clays. Maya potters had a thorough knowledge of the

different properties of the available natural resources, including their thermal behavior, to make a functional vessel. Learning about the physical and chemical properties of the clay bodies is important to determine the suitability of a vessel for cooking or storing different kinds of products (López Varela, 2005a). A wide range of techniques deriving from the physical, chemical, and natural sciences is helping archaeologists identify how potters chose to select raw materials and how natural resources were used to make pots to support numerous daily life activities, for everything from cuisine preferences to cave rituals.

Technological and characterization studies provide insightful information about the function of a vessel. Throughout the history of humankind, people have used objects differently from their intended function. When a cooking jar was placed in a burial site or a cave, it extended its meaning beyond the domestic realm into the underworld. With this knowledge, archaeologists may distinguish if a vessel was used for its intended function or if it was used to signify, empower, embody, and/or engender the living spaces of the Maya. Identifying the residues trapped in Maya pots reveal how these were used. Ultra-performance liquid chromatography (UPLC)/MS-MS Analysis has already detected the presence of *capsicum* in excavated Formative pots from Chiapa de Corzo (Powis et al., 2013). This same technique has yielded valuable information about the consumption of cacao through its identified residues in spouted vessels from Colha (Hurst, Tarka, Powis, Valdez, & Hester, 2002). Molecular archaeology, a developing field, has already been used to determine blood residues in Maya pots from Copán (Matheson, Hall, & Viel, 2009).

Raman spectroscopy is commonly used to investigate the mineralogical composition of materials and to investigate the making of paints. In the Maya region, Raman spectroscopy has provided information regarding the surface treatment of vessels from Copán but also, about the firing process of Maya pots (Goodall et al., 2009).

Pucte Brown (Photomicrograph PPL, width of field 2.5 mm)

Ceramics: Maya Pottery, Fig. 3 Microprobe analysis of Pucte Brown pottery (Micrographs by Daszkiewicz et al., 1999, illustration prepared by Sandra L. López Varela)

Basically, this study has successfully identified paint mixtures for each color applied to different ceramic types and estimated the firing techniques through the different phases of iron oxide (Goodall et al., 2009, p. 108). Microprobe analysis is another technique used to determine how Maya potters treated pottery surfaces. At K'axob, potters selected vessels with a calcareous matrix, with rhombohedral carbonates of coarse silt and fine sand fraction, to paint their surfaces. This fine textured fabric yields relatively flat surfaces, easily smoothed with a pebble. The use of microprobe analysis revealed potters used brushes to facilitate the application of several slip coatings (Daszkiewicz, Schneider, & Bobryk, 1999). Preparing the surfaces to display the images on a Saxche Orange Polychrome vessel, required the potter to apply a fine layer of engobe before adding an iron-rich red slip (Fig. 3). Engobe is liquid clay used to decorate a ceramic piece before it has been fired and usually applied before the piece has dried. The black color of Actuncan Orange Polychrome contains both manganese and iron, contrasting with the iron-rich red slip. Black paint on Ixcanrio Orange Polychrome and Saxche Orange Polychrome fragments contained manganese. By controlling the original oxidizing and reducing atmosphere, the potter achieved both a red and a black color. Additionally,

LA-ICP-MS analysis of the chemical composition of the exterior slips, and red and black pigments of vessels originating from the central Petén lakes region of Guatemala suggest the Itza and Kowoj used different pigments for exterior slips and decorative motifs (Cecil & Neff, 2005).

In dating Maya pottery with instrumental techniques, thermoluminescence has not been successful for dating samples with a sedimentary origin (Wagner, Haberman, & Wagner, 1999). Additionally, archaeointensity determinations on Maya incense burners from Palenque, supported by Mössbauer spectroscopy, have estimated their firing temperatures (Fanjat et al., 2013). However, limited comparative data restricts the possibility of establishing a trend of intensity variations in Mesoamerica (Fanjat et al., p. 168).

The availability of portable and noninvasive technologies, such as pXRF spectrometers, is about to change the ways we study Maya pottery in the field. The ability to collect compositional data rapidly from highly specific locations on individual artifacts and its nondestructive capacity, pXRF, is aiding investigations along the Motagua Valley in Guatemala and the Naco Valley and Cacaúlapa Valley in Honduras (McCormick & Wells, 2013).

A Social Analysis of the Making of Maya Pottery

A social approach to the study of Maya pottery is concerned about investigating how material culture expresses the ways we conceptualize the relationships between others and ourselves, and between us as ceramicists and the Maya in the past. In building ceramic sequences through the type-variety system, archaeologists have struggled to define the pottery, characterizing the Terminal Classic and the subsequent post-Classic period. Despite the observed persistence of pottery forms and wares through time, innovation and continuity have to be accommodated to the theories suggesting a foreign population took over Maya Lowlands sites, putting an end to

Maya culture around AD 800 (Adams, 1971; Sabloff, 1973; Sabloff & Willey, 1967). Over the course of new excavations, we have learned fine paste pottery, a considered trait of such population, was not exclusively made during the Terminal Classic; alternative regions were producing the pottery, even during Formative times; and the pottery did not always display militaristic images (Bishop & Rands, 1982; Foias & Bishop, 2005; Lopiparo, Joyce, & Hendon, 2005; López Varela, 2005b; Rands, 1987). Instead of searching for answers as to why new forms were introduced at a time of political turmoil and environmental change, analysts are concerned about fitting innovation and continuity in pottery making as exceptions to the beginning-end cycle ceramic complexes are forced to express. Ceramic sequences are references for the archaeologist to measure time. Classifications are distant from the ways Maya peoples in the past constructed time and experienced meaningful times. These sequences have constructed “Maya” time following a plot (Hodder, 1995, p. 164), having a beginning (Early Classic period), a climax (Late Classic period), and an end (Terminal Classic period). In other words, this literary process has governed the ways analysts analyze pottery data.

Increasingly, archaeologists in the Maya region are becoming interested in learning how social values are communicated through different kinds of objects and their uses (Jackson, 2009; LeCount, 2010; López Varela & Dore, 2005; Luke, 2012). In approaching the ways people have used objects or natural elements for daily life activities (Meskell & Preucel, 2004), there is a genuine interest in learning about how individuals in a society communicate their particular values through objects and natural elements (Buchli, 2004; Hodder, 2004; Hoffman & Dobres, 1999; Pfaffenberger, 1999). At the Institute of Archaeology at Belmopan, there is a distinctive piece of pottery, an orange, nonglazed piece, recovered from Actun Chanona, a cave located at the base of the Sibun Gorge in Belize. This lion effigy bears a remarkable resemblance to those found in the Lion’s Courtyard of the Alhambra in Granada, Spain. These lions

conveyed the Quranic and Biblical images of paradise, a garden associated with four rivers, sprouting from the lions’ mouth. All of these elements – water, plant fertility, directionality, and the transition of humans into a paradisiacal world – were shared concepts with the Maya. Meaning does not reside in the object itself or in its immediate surroundings, but in the way we make sense of the object. The social embedded in material culture communicates its materiality, but only if we are familiar with the meaning objects intend to convey. Within this sense of materiality and agency, it is essential to recognize both elements, the social and the natural, are intertwined, both constructing individuals and the space they live in. Learning about the “social life of things” is a theoretical approach contributing to an understanding of the spatiality of objects, to the ways people organize living spaces and how these objects define their being in the world (Tuan, 1977; Low & Lawrence-Zúñiga, 2003).

The social analysis approach favors the use of material sciences to learn about the physical and chemical characteristics of the object. Analytical techniques address the influence of the chemical and physical properties in the selection of raw materials and preparation of the clay body to achieve specific technological and functional properties. Reconstructing the step-by-step process of a given technology requires a set of interpretative questions surrounding the object of production, examining the data with material science analyses and experimentation. The social analysis of Maya pottery has incorporated the *chaîne opératoire* or operational sequence as central to the study of technologies (López Varela, McAnany, & Berry, 2001). The intrinsic hermeneutics of the operational sequence guides the investigation to reveal the social diversity of humankind by approaching the choices made all the way through it. A social approach to the analysis of Maya pottery, therefore, questions if the ratios of raw materials really influence the physical and chemical properties of the body or if there are other reasons guiding their specific use.

In fact, the concern of using instrumental techniques to define human behavior originates from

analysts doing ethnoarchaeology (Arnold, 1971, 2005). Ethnoarchaeological studies have been crucial in learning about pottery production (Arnold, 1971, 1978, 1991; Deal, 1983, 1998), despite the making of Maya pottery in the past may not be compared easily with a modern context. Indirectly, ethnoarchaeological studies as a comparative procedure to learn about the past from the present suggests people and their social values, concepts, representations, and symbols have remained unchanged (Hodder, 1982, p. 16) throughout their living of historic events. The social logic of our actions, our being in the world, indeed is embedded in history and tradition, so the detachment with the past is not absolute either. However, assuming people can live unaffected for 500 hundred years of historic events entails some naïveté (Thomas, 1996). In the future, ethnoarchaeological studies could dedicate its efforts to address the social changes incited by economic development in the Maya region (Arnold, 2008). Development policies are becoming powerful erasers of social memory and traditions through infrastructure building and welfare policies inviting potters to change the technology of pottery making and restricting the availability of natural resources.

Identifying Maya Potters in the Pots Left Behind

Archaeological research has provided further evidence of pottery making and tools (López Varela et al., 2001; López Varela, van Gijn & Jacobs, 2002). Already, analysts have identified different kinds of firing features, ranging from open hearths to double-chamber kilns (López Varela et al., 2001; Lopiparo et al., 2005; Urban & Schortman, 2004). The seminal work of Anna O. Shepard (1956, 1964) stated the relevance of investigating the technological character of Maya pottery (e.g., Angelini, 1998; Daszkiewicz et al., 1999; López Varela et al., 2002). Results deriving from these studies describe the sequence of steps, transforming natural resources into meaningful and functional objects. The chaîne opératoire (operational sequence) (Leroi-Gourhan, 1943–1945), as an analytical concept, leads to an investigation of the decisions made by the

producer, in the use of natural resources to make a particular form. The decisions made by Maya potters encountered recognition in the archaeological record (López Varela et al., 2002). These decisions related to their selection of tools for the making of Late Classic vessels. Basically, potters chose to recycle broken pieces of pottery to make their tools for smoothing, scraping, incising, polishing, and boring. To make ceramic fragments suitable as tools, the edges need to be shaped; otherwise, it would be difficult to hold the piece with the fingers to perform a smoothing or scraping activity. Also, potters worked the edges of the sherds to create particular geometric forms and sizes. Selecting the shape of the pottery tool represents another choice to determine the effectiveness and performance of these implements. In the case of small tools, the angles allow reaching the joints quite easily, facilitating shaping, and retouching of the vessel (López Varela et al., 2002). These shapes adapted to the pottery grammar of simple clean curvatures and preferable angles characteristic of the Late Classic vessel repertoire (Fig. 4).

Not all pottery fragments made useful tools. Potters intentionally selected broken pieces of pottery, considering the characteristics of the fabric over hardness. Still, potters needed tools to perform a particular task. Fragments were selected considering the texture properties of the fabric and the adhesive bond power of particles, as these affect resistance to abrasion (Fig. 5). Tools used for scraping, characterized by a fabric containing angular, coarse, crystalline calcite, and rare grains of quartz, facilitated its use in such activity. Most tools were made from jars with a high frequency distribution. Broken pieces of jars or bowls could be recycled to fabricate the necessary tool fairly quickly, according to our experimental studies (López Varela et al., 2002). Consequently, cost was a factor in the making of Maya pottery.

The chemical and physical properties of the natural resources condition not only form and function but also the objectification of the social. For instance, vessels with a calcareous matrix (a substance containing calcium carbonate), according to chemical analyses, were not used

Ceramics: Maya Pottery,

Fig. 4 Experimental use of a triangular tool (Photographs by Eric Mulder. Illustration by Sandra L. López Varela)

Ceramics: Maya Pottery, Fig. 5 Examples of scraping pottery tools (Photographs by Annelou van Gijn. Illustration by Sandra L. López Varela)

in cooking or in any other activity involving their use in a fire atmosphere. Most pots with a calcareous matrix exhibited appliqué, slip clay, or paint, such as Hillbank Red or Saxche Orange Polychrome. On the contrary, vessels with a noncalcareous matrix and coarse crystalline calcite, added as temper, allowed their exposure to fire (Daszkiewicz et al., 1999). Most striated jars from the Formative to the post-Classic period have a non-calcareous matrix. We learned potters changed their recipes to make pots, as jars of the Encanto Striated type contain aggregates of grog and clay in its noncalcareous matrix. Adding

grog represents another choice the potter had to make either because it was necessary to recycle pottery against the lack of resources or the need for experimentation. There is evidence of the making of new recipes to make jars for post-Classic times, as the body shows large crushed particles of calcite causing the jars of Piste Striated to bloat (Figs. 6 and 7).

To acquire their raw materials, Maya potters did not have to move a long distance. There is evidence potters were quarrying in the surroundings of the pottery workshop found at K'axob (López Varela et al., 2001). In the surroundings of this workshop, 9 roughly rectangular blocks of fine-grained consolidated sediment share physical attributes, such as texture, with Belize Red pottery, easily recognized by its thin walls and fine-grained but gritty paste composition. Their size and shape are ideal for tumpline (a band or strap strung across the forehead or chest to support a backpack) or canoe transport. Samples of Belize Red type, originating from excavations at Barton Ramie, showed the gritty texture of Belize Red was attributable to fragments of pumice and volcanic glass and, to a lesser extent, grains of calcite (Gifford, 1976, p. 255). The analyzed sample from K'axob is characterized by a noncalcareous matrix with grains of quartz and aggregates of

Ceramics: Maya Pottery,

Fig. 6 Examples of Society Hall vessels with a calcareous matrix (Photomicrographs by Daszkiewicz et al. (1999). Illustration by Sandra L. López Varela)

**Ceramics: Maya Pottery,**

Fig. 7 Examples of vessels with a noncalcareous matrix could have withstand fire exposure (Photomicrographs by Daszkiewicz et al. (1999). Photographs and Illustration by Sandra L. López Varela)

cryptocrystalline calcite. The composition is not common in the chemically analyzed samples. The making of Belize Red shows potters accommodated the available natural resources to fulfill social demands (López Varela et al., 2001).

Maya potters received or provided stylistic and form conventions from and to a large-scale sphere of influence includes, at various times, the Peten, the Teotihuacan, the Usumacinta-Pasión regions, and the Yucatan. These pots represented

individuals' thoughts and actions, such as the making of the tripod cylinder vessel of Early Classic times. The vessel form was used as far as Teotihuacan and has appeared in numerous contexts in the Maya region (Varela Torrecilla & Braswell, 2003).

In the Maya region, social identity and power was displayed on painted vessels, such as those of the Saxche Orange Polychrome type. Most painted images are displayed on the outside surfaces of vases or the bottom of a dish.

Preserving the Knowledge of Maya Potters

In writing about the social in the making of Maya pottery, it is of concern to me the reader understands potters in the past had a thorough knowledge of physical and chemical properties. The type-variety system is a valuable tool to the study of the Maya knowledge. However, the use of analytical techniques is the most reliable avenue of research to investigate how pottery was made. The technological knowledge of Maya potters should be investigated and preserved with the use of instrumental techniques, experimental studies, and application of emerging theoretical paradigms.

The word technology could be inadequate to refer to the steps of how pottery was made in the Maya region. Reading the past in the realms of technology simply represents our ways of seeing the world of how potters expressed, materialize, and mediated social relations through the pots they made. My suggestion, now followed by other analysts, to investigate the social aspects of Maya pottery results from the long-time quest in archaeology of providing a human face to the pots and sherds that we excavate.

Ceramics: Mimbres Pottery

Michelle Hegmon

Mimbres pottery, made primarily in southwestern New Mexico between 750 and 1150 AD, is renowned for its spectacular, often naturalistic, black-on-white designs (Fig. 1). Although painted pottery is common in the archaeological record of the North American Southwest, Mimbres pottery stands out because of its elaborate representational designs, which depict everything from the ubiquitous rabbit to scenes of everyday life and apparently mythical creatures. Because of the pottery's beauty and appeal to collectors, many Mimbres archaeological sites have been destroyed by looters searching for pottery to sell, and irreplaceable information about the past has been lost.

Mimbres, from the Spanish for “willows,” is the name given to a small river in southwest New Mexico. The name came to be applied to the pottery found in archaeological sites along the river, and eventually to the people who made the pottery. However, it is important to keep in mind that these are labels applied (mostly by people of European descent) to pre-Hispanic Native Americans. We do not know what the people called themselves, although we can be sure it was *not* Mimbres. In fact, recent approaches in archaeology have attempted to decouple pottery styles and cultural identity, and have challenged the extent to which the people who made the pottery we call Mimbres were

Ceramics: Mimbres Pottery, Fig. 1 Classic Mimbres Black-on-white bowl from Ronnie Pueblo (Nelson, 1999, pp. 96–97). The bowl is part of the permanent collections of the Museum of Anthropology, Arizona State University

united culturally, socially, or politically. They were maize farmers living in fairly simple hamlets and villages that housed from a few households to a few hundred people. They had no writing, draft animals, or metal tools. And while their social organization was elaborate in many ways, they did not have a well-developed political hierarchy or marked social inequalities. Syntheses of Mimbres archaeology include Anyon, Gilman, and LeBlanc (1981), Hegmon (2002), Hegmon et al. (1999), LeBlanc (1983, 1989), and Nelson (1999) and a recent issue of *Archaeology Southwest* (2003). Book-length treatments of Mimbres pottery, especially the designs, include Brody (1977, 2004), Brody, Scott, and LeBlanc (1983), Brody and Swentzell (1996), Fewkes (1989), Kabotie (1982), LeBlanc (2004), Moulard (1984), and O’Bagy Davis (1995). In addition, reports on Mimbres sites include numerous pictures and analyses (e.g., Anyon & LeBlanc, 1984; Cosgrove & Cosgrove, 1932; Shafer, 2003).

Situating the Pottery in Time and Place

The Mimbres region (Fig. 2) is part of the larger Mogollon archaeological culture area, which

Ceramics: Mimbres Pottery, Fig. 2 Map showing the Mimbres region in southwest New Mexico and surrounding states

includes much of southern New Mexico and northern Chihuahua, as well as central Arizona. Mogollon pottery, made with iron-rich volcanic clays, is generally brown or red in color, while pottery made in the northern Southwest (what had been called the Anasazi area but is now more properly known as Ancestral Pueblo) is generally white or gray, sometimes with black designs. Because Mimbres pottery is black-on-white, it was initially thought to be northern in origin. However, it is now well known that Mimbres pottery is indeed a Mogollon brown ware, covered with a thin slip of white clay that provides a backdrop for the black designs. The local development of Mimbres pottery – from plain brown to red-on-brown to red-on-white and finally to black-on-white – is well understood and well dated (see especially Anyon, Gilman, & LeBlanc 1981; Scott, 1983; Shafer & Brewington, 1995; Shafer & Taylor, 1986). Because the

painting style changed fairly rapidly, archaeologists are able to date the pottery quite precisely. For example, Fig. 3 illustrates a bowl with a design that extends all the way to the rim and that has straight-line hachure with framing lines thicker than the hatch lines; these are both relatively early characteristics and together they indicate that this bowl should be classified as Early Style II (ca. AD 880–920; Shafer & Brewington, 1995). Later designs (generally classified as Classic Mimbres Black-on-white or Style III, and illustrated in Figs. 1, 4, 5, 6, and 7) have various kinds of rim framing lines. Scott (1983) illustrates the stylistic changes over time, and Shafer and Brewington (1995) present a detailed microstyle chronology. Mimbres pottery includes various forms including storage and cooking jars as well as bowls. However, most of the painting and virtually all of the representational designs are found on bowls. Painted pottery was most elaborate and

Ceramics: Mimbres Pottery, Fig. 3 Style II Mimbres Black-on-white bowl from the Galaz Ruin (Anyon & LeBlanc, 1984, Plate 12a) (Photo courtesy of the Mimbres Archive [#2963]). The bowl is part of the permanent collections of the University of Minnesota)

Ceramics: Mimbres Pottery, Fig. 4 Jackrabbit depicted on Classic Mimbres Black-on-white bowl from the Swarts Ruin (Photo courtesy of the Mimbres Archive [#2051]). The bowl is part of the permanent collections of the Peabody Museum, Harvard University)

probably most common during the Mimbres Classic Period (1000–1130 AD), and painted bowls at that time had an average volume of 2.2 l (based on data from the Galaz Ruin Anyon & LeBlanc, 1984, p. 169).

Chemical and mineralogical analyses (summarized in Gilman, Canouts, & Bishop, 1994) clearly indicate that Mimbres pottery was made in many locations and villages; it was not centrally produced. The elaborateness of the designs suggests that some may have been produced by specialists, but if this were the case they were likely part-time specialists. Recent calculations (Le Blanc, 2004) suggest that all Mimbres black-on-white vessels could have been made by just a few potters, each making only 50–100 pieces annually. While most pottery makers and painters in the pre-Hispanic Southwest were probably women, several authors have suggested that at least some of the Mimbres designs were painted by men, because they depict rituals probably controlled by men (Brody, 1977) and because the birth scenes are anatomically unusual (Hegmon & Trevathan, 1996). The issue is controversial, and a clear resolution is unlikely.

Mimbres painted pottery is found in many contexts, including in trash middens, on living floors, and in burials, across the Mimbres region. Many burials – in simple pits in middens and under house floors – were interred with a bowl placed over the skull. Most of these bowls had a small hole carefully punched out of the base (see Figs. 3 and 6); these bowls are said to have been “killed,” and some have speculated that the hole allowed the deceased’s spirit to escape. Many of the bowls found in burials have wear patterns that indicated they had been used before they were interred (Bray, 1982). It is possible that most individuals had a bowl that they used for eating and other purposes, and that bowl accompanied them into the grave.

The Designs

Before considering the designs and their analyses, two caveats should be noted. First, although many designs appear to be realistic, in that they accurately portray details such as the topknot on a Gambel’s quail and the black tips on jackrabbit ears (Fig. 4) the corpus of designs as a

whole should not be assumed to reflect Mimbres life accurately. Rather, the pre-Hispanic artists – for various aesthetic, cultural, and social reasons – *chose* to depict certain scenes in certain ways. The designs are representations of what people believed should be portrayed on pottery, and they should be interpreted from this perspective. Second, as Brody (2003) has emphasized, the designs were painted on hemispherical surfaces (i.e., the interior of bowls) that were often placed below the user and viewer's eye level; most reproductions do not convey the designs' three-dimensional aspect or use context.

Mimbres pottery designs have been the focus of much attention, by archaeologists, art historians, and the public (Brody, 1977; Brody et al., 1983; Brody & Swentzell, 1996; Moulard, 1984), and much is known about what they depict. However, there is still a need for comprehensive quantitative analyses of the designs and their distribution, as I noted in my recent review (Hegmon, 2002). Designs with representational elements (Figs. 1, 4, 6, and 7) are less common than those that are purely geometric (Figs. 3 and 5) (221 versus 494 in the Galaz Ruin collection Anyon & LeBlanc, 1984). Most representational designs are depictions of animals native to the Mimbres region, some show scenes that include humans, and others depict apparently mythical creatures. Early Mimbres representational designs are similar to designs on pottery from the Hohokam region in southern Arizona, but by the Classic Period, the Mimbres style was unique.

Interpretations of the meanings of the designs are best made by considering their larger cultural context. Maize was a staple food in the Mimbres region, supplemented by other crops, wild plants, and meat from small animals such as rabbits, as well as occasional larger animals such as deer. In comparison, almost no maize or other plants are depicted on the pottery, and while there are many rabbit paintings (Fig. 4), there are few scenes (possibly only one in the known corpus) of rabbits being trapped or hunted. In contrast, quite a few paintings depict the hunting of larger animals, including bear and elk (Fig. 6). Taken together, these patterns support the argument that the paintings represent what people wanted

Ceramics: Mimbres Pottery, Fig. 5 Geometric design on Classic Mimbres Black-on-white bowl from the Galaz Ruin (Anyon & LeBlanc, 1984, Plate 23E) (Photo courtesy of the Mimbres Archive [#3033]. The bowl is part of the permanent collections of the University of Minnesota)

Ceramics: Mimbres Pottery, Fig. 6 Bear hunt depicted on Classic Mimbres Black-on-white bowl from the Galaz Ruin (Anyon & LeBlanc, 1984, Plate 83E) (Photo courtesy of the Mimbres Archive [#2902]. The bowl is part of the permanent collections of the University of Minnesota)

to emphasize (i.e., hunting), not what they actually ate. One unpublished but widely cited analysis (LeBlanc, 1977) found that bowls depicting certain animals were associated with certain

villages or areas, suggesting the animals were relevant more to social identity (e.g., as clan symbols) than to food.

While many of the animals depicted on the bowls would have been local to the Mimbres region, a number of exotic and probably symbolically important species are also depicted. In many cases, biologists have been able to identify particular species because the Mimbres paintings include relevant details, such as fin and beak shapes. Macaws, particularly their red feathers, have great ritual significance to contemporary Southwestern Native Americans, and a few macaw skeletons have been found in archaeological sites in the Mimbres region and elsewhere in the Southwest, suggesting that this ritual significance extends far back in time. Parrot-like birds are occasionally depicted on Mimbres bowls, and analyses of their traits indicates that most are scarlet macaws, native to the lowlands of southern Mexico and central America, more than 1,000 miles from the Mimbres region (Creel & McKusick, 1994). Similarly, analyses of the fish (and a possible whale) depicted on Mimbres pottery indicate that many are saltwater species, probably from the Gulf of California, approximately 640 km distant (Jett & Moyle, 1986). Thus it is clear that the people who painted the Mimbres designs had knowledge of distant regions, either through travel or trade and interaction.

In the past two decades, archaeologists have devoted significant attention to understanding women and gender relations in the past. Mimbres paintings give particular insights (see Hays-Gilpin, 2002) because some depict men and women engaged in various activities (almost all depictions of humans show them engaged in some activity; there are almost no simple portrait-like treatments). Some humans have clear sexual characteristics (breasts or penis), and inferences about styles of dress and body decoration associated with each sex make it possible to identify the sex or gender of many of the human figures (Munson, 2000). For example, when string aprons (Fig. 7) are depicted on individuals with clear-cut sexual characteristics, they are always associated with females; thus, string aprons

Ceramics: Mimbres Pottery, Fig. 7 Pregnant woman with parrot-like bird (possible macaw) depicted on a Classic Mimbres Black-on-white bowl from the Galaz Ruin (Anyon & LeBlanc, 1984, Plate 76F) (Photo courtesy of the Mimbres Archive [# 2845]. The bowl is part of the permanent collections of the University of Minnesota)

are interpreted as good indicators of gender (i.e., women). Drawing on this and similar analyses, Munson was able to conclude that there was a gendered division of labor in Mimbres society (men are more often associated with hunting, women with child care). However, there is at least one famous scene of a pregnant woman (seemingly triumphant) carrying a hunted antelope; this image graces the cover of a milestone volume on gender and archaeology (Gero & Conkey, 1991). Furthermore, although more men than women are depicted engaged in apparently ceremonial activities, women are consistently shown handling ritually important parrot-like birds (often macaws) (see Fig. 7).

Contemporary artists often state that their art conveys meanings that cannot be put into words, and it is likely that the same applies to art of the past. It is also likely that Mimbres pottery painting – done by perhaps hundreds of artists over approximately four centuries – conveys a range of meanings. However, researchers have gained some insights into the general range of meanings associated with the pottery. Because the bowls are often found in burials, and some

depict scenes from what appears to be the Puebloan World of the Dead, Brody and Swentzell suggest the images refer to “the unity of man and the cosmos, the living and the dead, and of the structures of harmony” (1996, p. 38). Moulard (1984) similarly concluded that the designs symbolize transformations, such as from life to death or childhood to maturity.

Collections

Mimbres pottery – particularly pieces with representational designs – has long had great appeal to collectors. The result has been the destruction and desecration of Mimbres sites. The large site of Old Town is well known for looking like a mine field because it is so full of large holes, many made by backhoes and bulldozers. Galaz Ruin (Anyon & LeBlanc, 1984), one of the largest Mimbres villages, no longer exists; it was completely removed by bulldozing. Much of this activity is illegal (i.e., it is illegal to disturb archaeological remains on public land, and it is illegal to disturb human remains even on private land), but law enforcement cannot always keep pace (Turnbow, 2001). In an attempt to stop the destruction and preserve some of what remained of Mimbres archaeology, Steven LeBlanc formed the Mimbres Foundation in the 1970s, and today the Archaeological Conservancy undertakes similar activities on a much wider scale (Blanc Le, 2003). Also, many responsible authors are today refusing to publish images of looted bowls so as not to increase their value (e.g., the second edition of Brody’s *Mimbres Painted Pottery* 2004), a strategy in line with the ethical guidelines of the Society for American Archaeology. Thus the situation is improving, though destruction continues (Turnbow, 2001).

The problem with collections is not simply private ownership of the remains of past Native American cultures. A more serious issue is that the demand for collections, and the high prices paid for Mimbres pottery on the art market, encourage the illegal looting of sites. And because many bowls are found in burials under

house floors, the search for pottery results in the destruction of architecture and the desecration of burials. People who want to possess privately the beauty of a Mimbres bowl are advised to purchase some of the well-made replicas available from various sources, including Laurel and Paul Thornburg of Sonoita, AZ.

The End of the Mimbres Pottery Tradition

The style, color, and sizes of the pottery we know as Mimbres changed, more and less rapidly, during the entire period of its production, from at least 750 to 1150 AD. It became less common by AD 1150, and it was certainly no longer made by the end of the twelfth century. Instead, people in the Mimbres region began using and making an array of different kinds of pottery. An understanding of the end of this famous style provides insights into how archaeologists understand prehistoric peoples. Again, “Mimbres,” is a Spanish word, a label we have applied to a river and a style of pottery, among other things. But the decline of the pottery does *not* mean the decline of a people. It simply is yet another example of a style change.

We know, through detailed studies of architecture and radiocarbon dates (Nelson & Hegmon, 2001), that people continued to live in the Mimbres region during the time that Mimbres pottery became less common. So why did the style change? Mimbres pottery is unique in the Southwest, and it is reasonable to think that it meant something special to the people who made it. Mimbres villages were among the largest and most densely populated in the Southwest at the time (with the exception of the Hohokam area in southern Arizona). Life in these villages may have been fairly difficult; the Mimbres Classic period was a time of environmental degradation, and eventually drought and subsistence stress (Minnis, 1985). The beauty of the pottery is not an indication of the ease of the artists’ lives. Rather, Mimbres pottery, especially the elaborate Classic period paintings, may have been part of the tradition of living in large villages, including

the hard times. Beginning by 1130 AD, many people left the villages and resettled in small hamlets, a process known as regional reorganization (Hegmon, Nelson, & Ruth, 1998; Nelson, 1999). As people resettled, they developed new social networks and learned about new styles, which they eventually adopted as part of their changing social identities. The new generation chose to make new styles of pottery for new reasons.

Ceramics: Rethinking Olmec Pottery

Jeffrey Blomster

Department of Anthropology, George

Washington University, Washington, DC, USA

After 1200 BCE (years presented in this entry are uncalibrated), distinctive ceramic vessels – Olmec pottery – appeared at select sites across the vast region that anthropologists refer to as Mesoamerica (southern Mexico, Belize, Guatemala, and eastern Honduras; Fig. 1). While exchange and interaction between regions existed prior to this time, in the case of Olmec pottery, the ceramic vessels display a consistent iconography that often contrasts with local pottery traditions. The iconography exhibited on Olmec pottery may represent developing religious beliefs, cosmology, and ideology, elements of which can be found in subsequent Mesoamerican groups. While features of religion and cosmology existed prior to 1200 BCE, Olmec pottery synthesizes and abstracts these concepts

on durable materials. As such, understanding the origin and spread of Olmec pottery has important implications on the nature of Mesoamerican civilization.

In discussing Olmec pottery, the focus here is only on the earliest Olmec ceramic phase, which corresponds with the ascendance of the site of San Lorenzo from 1200 to 900 BCE – often referred to throughout Mesoamerica as the San Lorenzo Horizon or Early Horizon (see Pool, 2007).

Mesoamerica Prior to 1200 BCE

For millennia after the adoption of agriculture, small villages – marked by very limited political organization and social differentiation – flourished throughout Mesoamerica. In the centuries before 1200 BCE, sociopolitical change began to occur. In the Soconusco region of coastal Chiapas, early chiefdoms of the so-called Mokaya people have been documented (Clark, 1991; Clark & Pye, 2000), where competing leaders vied for prestige and redistributed imported goods, such as obsidian (a volcanic glass). Each Mokaya chiefdom was centered on a main village, such as Paso de la Amada, where leaders lived in what were probably combinations of public structures and elite residences. The importance of and reliance on agriculture in these early villages remains an important debate, with great regional variation. In the Soconusco, for example, maize was a relatively unimportant part of the diet, used primarily as a prestige food (Clark & Pye, 2000).

By 1200 BCE, chiefdoms also appear in the Valley of Oaxaca and the Nochixtlán Valley in modern Oaxaca state. In the Valley of Oaxaca, where most small villages covered only 2–5 ha, the village of San José Mogote had a 20 ha “downtown” area of public structures and higher-status houses which contrasted slightly with normal houses in terms of quality of construction and plaster and the occasional outbuilding or ramada (Flannery & Marcus, 1994). Similar developments occurred to the northwest, where the site of Etlatongo became the head of

Ceramics: Rethinking Olmec Pottery, Fig. 1 Map of Mesoamerica, with modern national boundaries and Mexico City shown for reference. Important San Lorenzo

Horizon sites from which Olmec pottery has been analyzed are indicated

a small chiefdom in the Nochixtlán Valley. Beyond Oaxaca, chiefdoms are evident at the Basin of Mexico sites such as Tlapacoya and Tlatilco.

The Olmec and the San Lorenzo Horizon

Around 1200 BCE, all of the villages mentioned above exhibit a distinctive new style of ceramic vessels – Olmec pottery – that contrasts with local pottery traditions, which continued to be produced alongside Olmec pottery. While the origin of this pottery has been highly debated, the name applied to it – Olmec pottery, as well as the associated concept of Olmec style – has been criticized for linking this material with the archaeological Olmec people, who flourished at the Gulf Coast site of San Lorenzo, Veracruz, from 1200 BCE to 900 BCE (Blomster, 1998; Coe, 1968; Diehl, 2004; Grove, 1989; Pool, 2007). In this entry, the terms Olmec style and Olmec pottery are used separate from the Gulf

Coast Olmec, to indicate that the link between Olmec-style material culture scattered across Mesoamerica and the Olmec people of the Gulf Coast is one that must be robustly documented rather than assumed. Much of the problem with the incautious use of the terms “Olmec style” and “Olmec pottery” is that these concepts were created in the first half of the twentieth century by museum curators examining looted objects, lacking provenience, prior to the discovery and exploration of the archaeological Olmec (Blomster, 1998, 2004; Grove, 1996). Thus, many objects that have loosely been labeled “Olmec style” over the past 50 years have no actual correspondence with the Gulf Coast Olmec material culture. To really discuss the Olmec style and Olmec pottery from a Gulf Coast perspective, objects from excavated and well-documented Olmec sites must be employed to define it and then compared with the many disparate objects from throughout Mesoamerica that have been labeled as part of this style (Blomster, 2002; Coe, 1965).

Ceramics: Rethinking Olmec Pottery,

Fig. 2 Types of Olmec pottery at San Lorenzo, with exterior shown to the right of the profile. (a, b) Calzadas Carved pottery. (c) Xochiltepec White pottery. (d) Conejo Orange-on-White (Adapted from Blomster, Neff, and Glascock (2005, Fig. 2))

The location of San Lorenzo, on an artificially modified salt dome above the surrounding floodplain, seems to have been an important reason for the growth of this center, which Cyphers (1996, 1997, 2012; Symonds, Cyphers, & Lunagómez, 2002) estimates as close to 700 ha – dwarfing all contemporaneous settlements in Mesoamerica. San Lorenzo is almost an island among various streams and rivers, with soils constantly replenished by the Coatzacoalcos River. The San Lorenzo Olmec appear to have exerted a tight control over their immediate hinterland, with secondary sites deployed throughout the landscape for controlling the flow of resources (Symonds, 2000). Some archaeologists believe the Olmec at San Lorenzo represent a more complex form of political organization, perhaps an incipient state, while all other contemporaneous Mesoamerican regions featured chiefdoms. The debate over the sociopolitical organization of the Olmec has implications for their impact on other regions of Mesoamerica (see “[Extra: The Debate on Olmec Interaction](#)”).

Olmec artists created the first monumental art in Mesoamerica, including multiton basalt colossal heads – representing Olmec rulers – and large, rectangular thrones for leaders. The Olmec style is different from other Mesoamerican art styles in

formal qualities of shape, line, and space. This art is sculptural – made both in the round and in relief. In addition to the naturalistic imagery on monumental Olmec art, there is an iconographic or symbolic imagery that abstracts the important concepts of Olmec religion, cosmology, and ideology (Coe, 1965; Cyphers, 2012; De la Fuente, 1992). The sculptural nature of this style is expressed in pottery, where one of the important types (see below) features carved designs and symbols, some of which appear on monumental Olmec art.

Types of Olmec Pottery at San Lorenzo

In terms of Olmec pottery from San Lorenzo, four types have corresponding examples elsewhere in Mesoamerica (Fig. 2): Xochiltepec White, Conejo Orange-on-White, Calzadas Carved, and Limón Incised (Coe & Diehl, 1980).

Xochiltepec White pottery is made of clay so low in iron that it fires pure white. In terms of vessel shape, this type is frequently expressed in effigy vessels that represent squashes, usually without additional decoration. Conejo Orange-on-White represents a related – and even scarcer – type (Coe & Diehl, 1980, p. 179).

It exhibits the same paste as Xochiltepec White but has an orange slip, through which potters sometimes carved designs – contrasting the orange with the underlying white of the paste.

Calzadas Carved pottery exhibits distinctive carved Olmec-style symbols. Many of these stylized images contain elements of possible supernaturals referred to as the fire-serpent and were-jaguar, represented by what has been interpreted as flame eyebrows, crossed bands, opposed lines, and music brackets. Limón Incised pottery (which also includes some carved motifs) represents more abstract designs, which generally occur on the exterior of the vessel. Incised lines form curvilinear designs, emphasizing the *ilhuitl* or opposed volutes motif. Limón Incised pottery is less evident in ceramic assemblages outside of the Gulf Coast compared with Calzadas Carved.

Olmec Pottery in Oaxaca

As my work has focused on Oaxaca state, I discuss primarily the Olmec pottery present in San Lorenzo Horizon villages in the Valleys of Oaxaca (home of the Zapotec people) and Nochixtlán (home of the Mixtec people). Sherds – broken pottery vessel fragments – of Calzadas Carved and Xochiltepec White have been excavated in the large village of San José Mogote (Flannery, 1968), as well as secondary sites such as Tierras Largas (Winter, 1972), in the Valley of Oaxaca. Vessels that feature Olmec designs in Oaxaca, such as Leandro Gray and Delfina Gray (Fig. 3), have been interpreted as locally made without any priority by the Olmec in their creation (Flannery & Marcus, 1994) – an example of a “peer polity” model (see “Extra”). Accumulating evidence from both the Gulf Coast and Oaxaca, however, suggests a more complicated scenario.

Excavations at Etlatongo, in the Nochixtlán Valley (Blomster, 2004), recovered a large sample of Olmec pottery in an area once characterized as peripheral to the Valley of Oaxaca in terms of both sociopolitical complexity and interaction (Marcus, 1989). In addition to examples of

Ceramics: Rethinking Olmec Pottery, Fig. 3 Examples of gray Calzadas Carved pottery from Oaxaca. *Left* from San José Mogote, *right* from Etlatongo (Photo by J. Blomster)

Ceramics: Rethinking Olmec Pottery, Fig. 4 Cylindrical Calzadas Carved bowl excavated at Etlatongo but through compositional analysis determined to be an import from San Lorenzo (Photo by J. Blomster)

Calzadas Carved (Fig. 4) and Xochiltepec White vessels, types of Olmec pottery that have largely not been reported from the Valley of Oaxaca – Limón Incised and Conejo Orange-on-White (Fig. 5) – have also been recovered at Etlatongo. Thus, it appears that Etlatongo has a fuller suite of Olmec pottery types than the large chiefdom centered at San José Mogote.

Ceramics: Rethinking Olmec Pottery, Fig. 5 Conejo Orange-on-White vessel excavated at Etlatongo but through compositional analysis determined to be an import from San Lorenzo (Photo by J. Blomster)

Compositional Approaches to Olmec Pottery

The origin of Olmec pottery proved elusive through primarily stylistic analyses. If the peer polity model or “sister culture” model is correct, Olmec pottery made in Oaxaca should occur readily at San Lorenzo, while sites like San José Mogote should have little imported Olmec pottery. Oaxacan graywares – Leandro and Delfina Grays – have been interpreted as produced in the Valley of Oaxaca and exported to Tlapacoya and San Lorenzo (Flannery & Marcus, 1994).

In order to determine more robustly the origin of Olmec pottery, chemical characterization techniques were used. Approximately 1,000 archaeological pottery and modern clay samples from the Gulf Coast, Oaxaca state, Chiapas, and Central Mexico were subjected to Instrumental Neutron Activation Analysis (INAA) at the University of Missouri Research Reactor. This was a collaborative process, with specialists from both archaeology and compositional analysis contributing to the database and its analysis (Blomster, Hector, & Glascock, 2005; Neff & Glascock, 2002). The INAA process determines the basic chemical composition of a sample through the measurement of various forms of radiation emitted as the radioactive isotopes in an irradiated sample decay. After counts of

concentrations of 32 elements have been performed, the chemical data are then analyzed in order to recognize compositionally homogeneous groups within the sample; these groups represent geographically similar zones. Samples that fall within these groups originate from the same geologic zone and are more similar to each other than samples from other zones.

Through INAA, it was possible to determine the compositional group and region of origin for 726 archaeological samples of Olmec pottery (Table 1). The results fundamentally change the way in which the production and distribution of Olmec pottery is modeled (Blomster et al., 2005).

The San Lorenzo Olmec produced both fine white paste pottery (Xochiltepec White and Conejo Orange-on-White) and decorated Olmec-style pottery (Calzadas Carved and Limón Incised) and exported them to other regional centers across Mesoamerica. Clays collected from various sites around San Lorenzo demonstrate the close chemical relationship between ancient Olmec pottery and modern clays in this region. Some Olmec pottery from other parts of Mesoamerica is in the same compositional group as those manufactured at San Lorenzo. Most regional centers produced local variants of Olmec pottery (Fig. 6), with much variation between regions.

Table 1 documents that the local variants of Olmec pottery were not exchanged between these villages. Of special interest is the data from San Lorenzo itself. A total of 203 archaeological pottery sherds were tested from San Lorenzo, and none of them come from Oaxaca or any other part of Mesoamerica. Calzadas Carved sherds found at San Lorenzo that appeared most similar to “Oaxacan variants” (Flannery & Marcus, 1994) were included in the sample to determine if Oaxacan villagers exported Delfina and Leandro Gray pottery to the Gulf Coast. Contradicting a central tenet of the peer polity model, none of the locally produced Olmec-style pottery in the sample was exported to the Gulf Coast. Instead, pots without Olmec designs, or truly localized renderings of them, may have circulated. One sherd from Etlatongo, in a style more similar to San José Mogote than anything else at Etlatongo (or San

Ceramics: Rethinking Olmec Pottery, Table 1 Regional assignments for San Lorenzo Horizon pottery (Adapted from Blomster et al. (2005, Table 2))

Ceramics: Rethinking Olmec Pottery, Fig. 6 Small Calzadas Carved vessel determined through compositional analysis to have been made at Etlatongo, where it was excavated (Photo by J. Blomster)

Lorenzo), has a composition suggestive, but not definitive, of a Valley of Oaxaca origin.

While it is possible that if every sample of Olmec pottery at San Lorenzo could be tested, a few may come from outside of the Gulf Coast,

this does not impact the general findings of this study. The Olmec at San Lorenzo generally did not receive foreign-made variants of Olmec pottery; the Olmec were its primary exporters.

Olmec pottery and associated symbols were valued by elites at the largest chiefly centers in Mesoamerica. While regions outside of the Gulf Coast made their own unique innovations and contributions to local versions of Olmec pottery, it does not appear that these other regions contributed substantially to the assemblage of Olmec-style symbols employed beyond each region. The Olmec appear to have been the primary disseminators of this pottery, which often displays rich iconography. Furthermore, important villages in adjacent regions such as San José Mogote and Etlatongo received pottery from the more distant San Lorenzo rather than from each other. It is also possible that potters, or their practices, moved and linked producers in disparate regions of Mesoamerica.

The Olmec interacted with groups across Mesoamerica that were already chiefdoms; both the Olmec and regional groups had various

interests in this interaction. The symbols exhibited on Olmec pottery suggest the dissemination of elements of Olmec religion and cosmology, which may have been received and utilized in widely different manners based on the interests of regional leaders and negotiations between and within local populations. Indeed, a fascinating aspect of this interaction is local emulation and appropriation of these symbols.

There was no one way in which these pots and symbols were disseminated across Mesoamerica. While some regions had limited, if any, entanglement with these materials and/or practices, at least one site, Canton Corralito in the Soconusco region (close to Paso de la Amada in Fig. 1), evinces the full suite of motifs, as well as vessel forms and angles virtually identical to those at San Lorenzo. Ceramic samples subjected to INAA document clear imports from San Lorenzo. Canton Corralito has been proposed as an Olmec colony or enclave (Cheetham, 2010). While investigators in the Soconusco region propose that this interaction transformed the local population from Mokaya to Olmec (Clark & Pye, 2000), the impact in the Nochixtlán and Oaxaca Valleys appears to be substantially different and less profound. At Etlatongo, both imported and locally made Olmec pottery rarely exceeded 5–10 % of the total ceramic assemblage from discrete contexts (Blomster, 2004). Access to foreign produced versus local imitation may reflect increasing differences in social status within the Etlatongo society. In Central Mexico, the impact also appears limited.

Extra: The Debate on Olmec Interaction

Much of the debate over Olmec interaction revolves around two perspectives. The nuclear-linear or so-called “mother culture” school views the Olmec as a precocious group in terms of social complexity, synthesizing and disseminating traits essential to all Mesoamerican societies. While Covarrubias (1957) proposed the Olmec created Mesoamerican civilization, modern proponents reject this idea, arguing that while the Olmec had achieved a different level of

sociopolitical complexity than their contemporaries, they interacted with groups that already exhibited complexity (Diehl, 2004). Due to the charged nature and contested meanings of the term “mother culture,” scholars who explore Olmec influence in Mesoamerica attempt to move beyond this term by focusing on the actual impact of the Olmec outside of the Gulf Coast (Neff et al., 2006b).

The peer polity model or so-called “sister culture” school views the Gulf Coast Olmec as just one of many groups utilizing a shared symbol set with other regions of Mesoamerica, without any priority in developing these symbols or attainment of a fundamentally greater level of social complexity (Flannery, 1968; Flannery & Marcus, 1994). Proponents of this perspective view the Olmec as a chiefdom, although the ongoing research at San Lorenzo (Symonds et al., 2002) demonstrates the more complex sociopolitical organization of the Olmec relative to contemporaneous groups.

Peer polity supporters (Flannery et al., 2005; Stoltman et al., 2005) contest the results of the INAA of Olmec pottery project, claiming a different approach to analyzing the ancient pottery – thin-section analysis (which looks at specific minerals in sherds) – contradicts the results of the INAA, viewing one method as superior to the other. The reality is these two methods complement each other. The conclusions of the Flannery and Stoltman group lack a substantive sample of local geology around San Lorenzo. Their claim, for example, that the volcanic materials in pottery excavated at San Lorenzo prove they are made in Oaxaca (Stoltman et al., 2005) founders on the fact that volcanic materials are also present in soils around San Lorenzo, as documented by a petrographic analysis from the Cyphers project at San Lorenzo (Neff et al., 2006b). The INAA project (Blomster et al., 2005; Neff et al., 2006a) documents that the Gulf Coast Olmec produced and disseminated Olmec pottery. While this research contributes to a stimulating debate on Olmec interaction and contrasting scientific methods, basic questions about what the Olmec and the various groups received from this exchange await further exploration.

Chao Yuanfang

Fabrizio Pregadio

Virtually the only known detail of the life of Chao Yuanfang, Chinese physician and medical author, is that he was Medical Erudite (*taiyi boshi*) at the court of the Sui dynasty sometime between 605 and 616. In that position he supervised the compilation of the *Zhubing yuanhou lun* (Treatise on the Origin and Symptoms of Diseases), the first Chinese text comprehensively devoted to etiology and symptomatology. The work, which is integrally preserved, was submitted to the throne in 610.

The 50 chapters of the *Zhubing yuanhou lun* discuss more than 1,700 syndromes, classified into 67 categories of internal and external diseases. The final sections are concerned with gynecology, obstetrics, and pediatrics. A special feature of the text lies in its therapeutic methods. Rather than ingestion of drugs or acupuncture, Chao advocated a therapy based on such practices as diet and *daoyin* (a set of bodily postures, similar in some respects to Indian *hatha yoga*). The ► [Huangdi neijing](#) (Inner Canon of the Yellow Emperor) provides the broad theoretical foundation to Chao's work.

The *Zhubing yuanhou lun* exerted a remarkable influence on the history of Chinese medicine, as reflected for example in the ► [Qianjin yaofang](#), written by ► [Sun Simo](#). It was highly esteemed in Japan as well, where it inspired the classification of diseases in the earliest extant medical compilation, the *Ishinpō*.

Chemistry in China

Anthony R. Butler and Christopher Glidewell

Of all the sciences in antiquity chemistry was one of the least understood. Until people had some comprehension of chemical elements, compounds, atoms, molecules, ions, and bonding, they found it difficult to make much sense of the chemical processes occurring naturally. This does not mean that there is no real history of chemistry; it means only that we should assess the early chemical practitioners on the accuracy of their observations rather than that of their interpretations. The modern Chinese term for chemistry is *huaxue*, the study of change, and what the ancient Chinese did well was to note and describe the chemical changes which were observed when substances were mixed, heated, dissolved, or treated in some way. The fact that their interpretation may seem a little abstruse by modern standards does not detract from the worth of their observations.

Before chronicling chemistry in ancient China it is important to understand exactly what had stimulated an interest in chemical processes. The Daoist religion sought to lead its adepts into such a harmonious relationship with the world that they would escape the horrors of disease and the tragedy of death. It was not life after

death but life without death, although the precise notion varied from age to age. Those who had discovered the *dao*, through meditation, study, forms of exercise, appropriate sexual activity, and purity of life, would retire to an isolated mountain retreat and there live in complete harmony with nature. They were called *xian* or “immortals,” nearer to gods than men. The idea of longevity as a reward for the godly life is not unique to Daoism; similar notions occur in Judaism. In the genealogy of the patriarchs we read, “And Enoch walked with God after he begat Methuselah three hundred years and begat sons and daughters” (Gen. 5²²). However, what is special to Daoism is the use of drugs to acquire immortality.

Until the Song dynasty, Chinese drugs were grouped into three classes: superior drugs which allowed one to realize vital powers, medium drugs to enrich one’s nature, and inferior drugs which cure disease. This particular classification is given in *Zhenghe bencao* (Herbal of the Zhenghe Era) and it is the superior drugs that became associated with the attainment of immortality. Initially the drugs were quite crude materials: minerals straight from the ground or dried herbs, but subsequent developments lead to the compounding of these “simples” to give “elixirs of immortality.” It was in the preparation of elixirs that the ancient Chinese made their first chemical observations.

The preparation of elixirs was not an activity associated with a popular or debased version of Daoism and abhorred by the more sophisticated Daoist adepts. Although the importance of elixirs in Daoist practice varied somewhat from dynasty to dynasty it always played some part in the pursuit of the Daoist goal. Several emperors of ancient China expended considerable effort to obtain the elixir of life. Shihuangdi (259–210 B.C.E.), of the Qin dynasty, equipped large expeditions under the command of Xu Fu and others to go abroad to uncover arcane secrets of preparing elixirs. Emperor Wu (156–87 B.C.E.) appointed numerous magic specialists to high positions.

Two prominent components of Daoist elixirs were cinnabar (mercuric sulfide) and gold. The

reasons for this selection are not difficult to appreciate. Cinnabar is bright red, reminiscent of healthy blood, and it was thought that the infusion into the body of extra healthy blood would enhance health and lifespan. The absence of understanding of chemical composition among the ancient Chinese meant that the physical appearance (i.e., the color) had greater significance than the obviously different chemical properties of cinnabar and blood. Gold was probably the most prized component of an elixir because it was obtained from the ground in an uncombined (and thus, uncorrupted) form and in the air it did not tarnish. If these attributes could be acquired by the human body then it would, indeed, last forever. One difficulty recognized by Chinese alchemists was that both cinnabar and gold are insoluble in water and, therefore, unlikely to be absorbed in the body. Much effort, therefore, was expended in devising methods of solubilizing both cinnabar and gold.

A manual in the Daoist Patrology (*Dao Cang*) entitled *Sanshi liu Shui Fa* describes the use of niter (potassium nitrate) in vinegar (dilute ethanoic acid) to bring numerous minerals, including cinnabar, into solution. In some cases there appears to be some confusion between solution and suspension; in other cases solution would occur in any aqueous solvent. However, in a few cases, particularly in the solubilization of cinnabar, some interesting chemistry is involved. A solution of pure niter in pure aqueous ethanoic acid has no effect on cinnabar but solubilization does occur if chloride ion is present as an impurity. This is probable as niter was obtained from marine sources. Thus the fanciful descriptions of Chinese alchemy may have a sound basis in chemistry if allowance is made for probable impurities. The same applies to an account in the *Sanshi liu Shui Fa* for the solubilization of gold where the required contaminant is iodate, a common impurity in crude niter deposits. The fact that these accounts of Chinese alchemical activity can be explained in modern chemical terms is evidence of the accuracy of the original observations.

Gold is not common in China and it was not regularly used as a form of currency. Because of

the shortage of gold, much alchemical activity was directed at making gold from more commonly available materials. This appears, at first sight, to be identical with European alchemical activity but the motivation was completely different. In Europe it was, until fairly late in the thirteenth century, the pursuit of wealth; in China it was from earliest times the pursuit of immortality. Cinnabar was a popular material upon which to work (gold and cinnabar often occur together in the earth) and the *Gui Jia Wen* contains the lines:

The span of life is up to me, not heaven.
The reverted cinnabar becomes gold, and millions of years are mine.

In the most famous alchemical manual (the *Neipian* of the *Bao puzi*) the author, ▶ [Ge Hong](#), gives a recipe for preparing gold from tin by heating with various forms of alum (potassium aluminum sulfate) on a horse dung fire. What was made was tin sulfide or mosaic gold, a yellow material which glitters just like gold. Present-day repetition of the procedure, using an electric furnace rather than a horse dung fire, confirms the production of tin sulfide.

The elixirs made from simples like cinnabar and gold contain, in general, so many components, some of which will contain impurities, that it is difficult to hazard a guess at what chemical changes are occurring. Picturesque titles were given to many elixirs. A mixture of calomel (mercuric chloride), cinnabar, sulfur, and realgar (arsenic sulfide) was known, according to the *Danjing Yaojue* of ▶ [Sun Simo](#) of the Tang dynasty, as Grand Unity Three Envoys Elixir. Needless to say, the elixirs did not have the required effect and their use in Daoist practice gradually died out, leaving only a memory of sustained but flawed chemical activity. There are just a few exceptions to this generalization of futility in Chinese alchemical activity, the most famous of which is the production of ▶ [gunpowder](#), known originally as *huoyao* or “fire drug”. Niter and sulfur are mentioned in early *materia medicas*, including *Shennong Bencao Jing* from the Han. Possibly in pursuit of elixirs, they were mixed and inadvertently

contaminated with carbonaceous materials, giving a material which burned very brightly. Careful adjustment of the proportions gave an explosive, used in China for firearms and civil engineering and for fireworks. The first printed recipe for gunpowder is given in a military manual, *Wujing zongyao* by Zeng Gongliang, printed in A.D. 1044. It was the optimized formula which traveled to Europe and had such a dramatic impact on the conduct of warfare. It is ironic that the most significant achievement of Chinese alchemists in their efforts to make elixirs of immortality was an instrument of warfare.

With a decline in interest in alchemy during the Yuan, Meng, and Qing dynasties, there was no emergence of modern chemistry from alchemical activity as there was in Europe. The advanced state of modern Chinese chemistry (epitomized by the laboratory synthesis of insulin in 1965) is due to the introduction of chemistry from the West during the nineteenth century, partly by missionaries and partly by young Chinese students studying in Europe and America. Among missionaries (although the term is not entirely appropriate) was John Fryer, the son of a poor English clergyman, who worked at the Kiangnan Arsenal translating manuals and textbooks for the Chinese government. Between 1867 and 1897 he acted as focal point for the propagation of western scientific ideas in China. Even during the political upheavals of the first part of this century, there was a general increase in Chinese scientific education, and a number of Western style scientific institutions, like the Peking Union Medical College, were established. In chemical research the dominant figure was Wu Xian. He completed his Ph.D. at Harvard Medical School in 1920 and returned to the Peking Union Medical School. By 1925 he was a full professor and initiated an extensive program of research into blood chemistry. Chemical research started elsewhere and, fueled by the innate talent of the Chinese people, it has grown, in spite of all the political upheavals of the Communist revolution and the downfall of Mao, to make China one of the leading nations in the world for chemical research.

Chen Yan

Hong Wuli

Chen Yan, a famous physician of the Southern Song Dynasty in the twelfth century, was born in Qingtian (now in Zhejiang Province), with Wuze as his surname and Hexi as his nickname. He was extraordinarily clever and proficient in prescription and pulse taking, as well as in treatment. It was said that he could prophesy the prognosis of incurable diseases. In 1161, he assembled a six-volume work of prescriptions, *Yi yuan zhi zhi* (Treatment Based on Etiology), with 81 categories which deals with the pulse and diagnosis of diseases, followed by their etiology, and the variorum of the *Canon of Pulsology*, all with relevant recipes. This work was never published.

Chen was especially interested in the study of pathogenesis. He claimed that the causes of all diseases could be divided into three categories; this was based on Zhang Zhongjing's hypothesis. Eventually, he compiled the *San yin ji yi bingzhang zhengfang lun* (Discourses on the Manifestations and Recipes of Diseases of Three Pathogenic

Categories) in 1174, in 18 volumes. He summarized all pathogens into three categories:

1. Endogenous emotional changes, the Seven Emotions (joy, anger, sadness, ratiocination, grief, apprehension, and fear), which originate from the internal viscera and affect the extremities.
2. Exogenous pathogenic factors, the Six Excesses (wind, cold, heat, damp, dry, and fire), which originate from the channels and affect the internal viscera.
3. Causes neither exogenous nor endogenous, which derive from immoderate food and drink, wounds, ulcers, and insect and beast bites. The etiological work exerted some influence on later generations.

Chen also summarized medical science in four Chinese characters, reading “title, substantial property application” claiming that all new commentaries on ancient classics could be categorized under four branches: sphymology, manifestation, disease, and treatment. Hence, all medical students should recognize a disease on the basis of pulsology and make a diagnosis on the basis of manifestations.

In the years 1165–1173, he compiled the *Herbology of Compiled Categories* with subheadings based on the above-mentioned ideas. Though it was an anonymous compilation with a “Preface by Master Hexi,” it was commonly believed to be Chen's.

Childbirth

Margarita A. Kay

The pelvic changes that evolved when hominids became upright walking creatures resulted ultimately in what is known as the “obstetrical dilemma” for humans. The woman's pelvic bones must not obstruct safe passage of the infant's head, and her soft vaginal tissue must be able to stretch to the maximum. Meanwhile, the baby must be mature enough to survive outside the woman's body but small enough to pass through her narrowed birth canal. Managing childbirth within these parameters developed throughout human history by means of observation, trial, and errors accommodated, however, by high fertility. Obstetrics conducted in hospitals is a recent biomedical specialty, and in the past decades, Western obstetrics has developed still more technologies. However, for non-Western mothers, little has changed in 2,500 years of written record. From that record, we can draw one of two opposing conclusions: first that childbirth customs are appropriate adaptations to biological needs; or, second, that high technology is always better than childbirth in a natural setting.

Some writers portrayed childbirth practices in non-Western societies as ideal, resulting in a quick and painless process. Men who were not allowed to observe births were told about them by informants who themselves also had been excluded from the birth scene. These writers believed that the non-Western woman just goes in the fields, gives birth, and returns to work in a few hours. Later, women anthropologists who observed non-Western births gave very different reports. Management of childbirth anywhere requires attention to the problems of safety, pain, fatigue, protracted labor, malposition of

the fetus, delivery, expulsion of the placenta, and healing. Solutions to problems are mandated by the universal physiology of childbirth. In Western obstetrics, these problems of childbirth are managed with technological equipment; in non-Western societies, the same problems are managed with hands.

Childbirth is not only a biological occurrence; it is also a sociocultural event. Differences in the management of birth reflect different values and beliefs. In some cultures, myth is used to explain pregnancy and birth. Sometimes birthing is a private process, sometimes a communal event. How a society reacts to physiological processes and the extent to which there is contact with other cultures accounts in part for diversity in the ways of managing childbirth. Each birthing system relates to the place women hold in a community, the value given individual children in that community's social structure, how much medical care is available and how it is distributed, and the religious belief system that is in place. Thus childbirth practices develop within the context of each particular society.

Such cultural strictures determine, among other things, how the pregnant woman should behave, who should take care of her, how abnormalities are to be explained and how to prevent them, what, it is believed, causes labor, how it should be stimulated, where the birth should take place with which persons in attendance, and what should be done after birthing for mother and newborn. Descriptions of diverse birthing practices can be found in the writings of George Engelmann and Hermann Ploss, Max Bartels, and Paul Bartels. Birth customs are catalogued in the *Outline of World Cultures*. MacCormack and Kay edited anthologies detailing birth practices in mostly non-Western cultures. Following are illustrations of some of this diversity from East India, Japan, Malaysia, the Navajo Nation, Seriland of the northwest coast of Mexico, Guatemala, Mexico, Ireland, and Ibo and Bariba tribal homelands in Africa.

Many “normal” activities of women are proscribed during pregnancy with the view of preventing childbirth difficulties. Some of these prebirth customs, are considered adaptive by

Western medicine. For example, pregnant American Indian women are urged to keep moving and working during pregnancy and to limit their intake of food. The goal is not to have too large an infant for easy delivery. In West Africa, on the contrary, women are fattened in order to make them desirable for marriage and childbearing. Each custom is beneficial: genetically, American Indian women tend to have very large infants, whereas the babies of African and African-American women are likely to be quite small.

The women themselves explain their customs only as "we have always done it that way." The outsider sees the rationale for many proscriptions deriving from principles of sympathetic magic, like affecting like. Ancient Mexicans and recent Navajo, for example, believe that weaving is dangerous during pregnancy because the umbilical cord will tie up the baby. This belief has a very long history. It is recorded as fact by ancient Greek authorities of Aristotle, Galen, and Soranus. Across Western and non-Western cultures, the woman and sometimes her mate are told to avoid certain foods and actions to prevent problems in birthing or abnormalities in the baby. Conversely, a woman's cravings for exotic foods must be satisfied or the baby will be marked. Some of the rules placed to solve birth problems may be seen in the belief system of the larger culture; for example, the *bidan kampung* (traditional midwives) of Muslim Malaysia consider the humoral system of Islam in selecting a western-facing direction (with modification for days of the week) to align the woman for birthing; west faces Mecca. For Navajo, on the other hand, it is vital that the mother's head *never* face west, for that is their direction for death. Women who are taught that congenital malformations are caused by unnatural phenomena wear amulets to protect the unborn child. Charms include medals, pictures, and prayers that represent their religion, iron filings, and pieces of crystal, coral, or jet. It could be said that magical thinking can also characterize high technological Western cultures, for childbirth outcomes cannot always be predicted. Rituals of testing are enacted to resolve anxiety of the unknown. Childbirth is feared to a certain extent by all people.

Non-Western women are given prenatal massages in many cultures, notably Japan and Mexico. The purpose of the massage is to fix the fetus in a position favorable for delivery. In some societies, the fetal position is also assisted by a belt around the woman's abdomen. The Japanese apply the maternal *obi* in a special ceremony in the fifth month of pregnancy. Mexican women wear a narrow red cord, which shows the ascent of the uterus. Traditional Navajo women maintain their custom of wearing a red belt woven with green figures, 5–6 in. in width, throughout pregnancy. This belt is later used during labor and delivery.

When a woman believes that her childbirth labor is starting, she takes herbal teas. Mexican women drink *té de manzanilla*, camomile tea, believing that if it is false labor, the tea will make the pains go away, and if it is true labor, the pains will come stronger and harder. This belief has pharmacological support. Navajo women use tea from a penstemon for the same purpose, or one from rabbitbrush. Ideally, the birth should be fast. Mexican and Guatemalan women are given the ancient Aztec herb *cihuapatli*, which has strong effects on the uterus. They are permitted little sleep but are encouraged to walk with their contractions to hasten delivery. When in pain they are allowed to scream, unlike West African Bariba and Ibo. The proud Bariba women attempt to deliver alone to conquer their fear. Traditional Navajo women were trained to make no sound in order to preserve the secrecy of the process and today are silent and motionless during labor.

Because childbirth is the obvious result of sex, women in societies that value female purity, innocence, and virginity have particular difficulties. Irish peasants hide their pregnancies as long as possible, and do not publicize births. Hindu women also do not advertise their condition, resulting in little attention to their prenatal health, and distressing labor. Following Biblical injunction, the laboring woman was expected to suffer, until in the mid-nineteenth century, Queen Victoria accepted the newly discovered anesthesia for her birthings.

In non-Western childbirth, a midwife conducts the birth process. She uses many ways to stimulate labor, from placing an amulet on the laboring woman or an axe under her bed, to giving herbal teas or some of the husband's semen for her to swallow. To lubricate the birth canal, she massages with whatever is typically available, such as lard, clarified butter (*ghee*) or cooking oil.

Posture during labor also varies. In many non-Western societies, the laboring woman is encouraged to keep an upright position, utilizing gravity to move the fetus in the birth canal. Anderson and Staugård summarized traditional birth positions of 22 tribes in Africa and found kneeling to be used in 12, squatting in 10, holding rope in 7, lying in 6, and half sitting in 5. These postures may relate to different pelvic dimensions; for example, women of Biafra commonly used the squatting position, which works best for women who have a short pelvic outlet. The 80,000 women who have had traditional genital surgery (female circumcision) present special challenges for safe delivery, because scar tissue does not stretch.

A common practice of American Indians has the woman in either a kneeling or squatting position, with one attendant supporting the woman from behind, pushing on the abdomen above the uterus, while another attendant is in front, pressing from below. The mother might be pulling on a rope during contractions. Or she might pull on a hammock, which is suspended above where she stands, as has been recorded for the Kalopalo Indians of Central Brazil. In the latter case, four attendants help the laboring woman, two pressing down on each shoulder, and two pressing on her feet to direct force during a contraction. Navajo women pull on the special red belt that they wore during pregnancy, looped over a beam in the ceiling. For the Seri, a hunting – gathering people of Sonora, Mexico, two women who are usually close relatives help with the birth. One assistant sits on the ground, her legs spread but her knees doubled under her, to make a lap for the parturient to sit on. The second assistant, also sitting on the ground but facing the laboring woman, holds her hands in position to receive the infant.

The parturient and midwives often wait for hours in the described positions. To speed the labor, the parturient may be given tea from the roots of indigenous plants, or a concoction of alcohol, limes, cinnamon, and aspirin. The women often say that they do not want to marry because childbirth hurts too much. Women of the nearby agricultural Yaquis drink an infusion of the narcotic plant *Datura* for childbirth pain.

For difficult deliveries, Punjabi midwives straddle the chest of the laboring woman, pressing hard on the abdomen with their hands; or they push with the heels of their feet on the pubic bone.

In matrilineal societies such as the Navajo, the attendants are commonly women from the maternal side of the family. Patrilineal societies such as Egyptian or Japanese, where descent is traced through the father's line, require the presence of the husband's kin, to assure continuity of the line. The birthing woman is accompanied by her husband's mother, and goes to her mother-in-law's house to recuperate from the birth.

Delivery of the placenta (afterbirth) is a grave concern in all societies. The medical ethnobotany of every group contains a variety of plants to give the woman whose placenta is slow to separate. According to humoral doctrines which are prevalent in many non-Western cultures including India, China, Middle America, and Latin America, those herbs that acted on the uterus were categorized as "hot" and "dry," and many of the same plant genera are used crossculturally. A retained placenta is a most dreaded complication of birth: "anyone can deliver a baby but it is the placenta which kills" (Bariba). Once the midwife delivers the placenta, she disposes of it according to its meaning in her culture, respect as a spiritual entity or fear of its power. In Malaysia, the placenta is considered to be the fetus's semi-human sibling, and thus is washed and ceremonially buried, which is similarly done by Guatemalans and Seri.

Some of the materials used to act on the uterus, either to bring on menstruation, stimulate labor, hasten birth, or separate the placenta, have been subjected to phytochemical analysis. *Artemisia* species, the botanical name first given by the

Greeks for their goddess of women, and used worldwide in Europe, the Middle East, China, Latin America, North America, and Mexico, contain estrogens, female hormones. *Matricaria*, named since Roman times from the Latin word for womb, relieves painful uterine cramps through its spasmolytic compounds. Analysis of other materials, such as the husband's semen, given to the laboring woman in some African cultures, shows that they are high in prostaglandins, chemical compounds used in biomedicine to initiate labor by causing the mouth of the uterus to begin opening.

Indian peoples of Mexico use plants passed down in oral history from Uto-Aztecan forbearers (such as *yyahautli*, marigold, to stimulate labor, and *toloache*, jimson weed, for labor pain) and also those learned from Europeans who came in the colonial period, coriander and rosemary, for their actions on the uterus. Hindu mothers are given Ayurvedic herbs, while Chinese herbs are used all over eastern Asia. Childbearing women take herbs for prenatal care, labor strength, and postpartum healing. The woman may drink the plant material in teas; it may be applied to her abdomen, inserted in her vagina, inhaled, or she may sit over infusions in vapor baths.

After the baby is born, the umbilical cord must be tied and cut, and again there are many practices to be followed. The cord is cut with a piece of sharp ► **bamboo** in Malaysia, a razor blade or broken glass in Ghana. It may be tied with hair, string, or animal tendon. The variety of dressings include pounded pottery, herbs, salt, ground shells, and ash, materials that can harbor bacilli causing neonatal tetanus. The cord remains may be buried in a place that is associated with the anticipated sex role behavior of the child. For example, a Navajo woman may bury her infant son's cord near the sheep corral and her infant daughter's cord near the weaving room. Mexican, Malaysian, and Japanese mothers kept each child's cord for the child's future welfare.

The immediate postpartum period lasts for 3 days in cultures predominately Christian, and 4 days in American Indian societies, the respective magic numbers for each. After giving birth,

and for a period of time prescribed by the culture, 20 days for many American Indians, 40 days for traditional Jews, Christians, and Muslims, the woman is supposed to be confined to her home. It is believed that the woman is vulnerable, requiring protection during the entire postpartum period. Some Mexican patients still observe *la dieta* during which time baths, walking barefoot, and otherwise being subjected to cold are proscribed. This includes avoiding "cold" foods, foods that are believed to have a quality of chilling the body.

The newly delivered woman is healed with heat in many cultures. The Navajo woman may have heat applied by warming green cedar and holding it to the abdomen with her red sash. She is bathed on the fourth day after delivery, especially if she had a ceremonial Sing during her labor. Her lacerations are treated with a salve of baked cactus, or a fumigant treatment may be prepared by digging a hole and heating stones therein. Soranus described a similar fumigant 2,000 years ago. "Mother roasting," as it is called, is a therapy used by many societies in Southeast Asia, including Malaysian. A fire is maintained beside the delivered woman for a prescribed number of days. This "dries out" the womb. A ritual fire is kept burning in the dwelling of the Seri woman for 4 days following the birth, in this case for the infant's sake. Hot leaves are pressed on the Ibo mother's abdomen, immediately after birth. The *temascal* or sudatory was used by ancient Aztecs after childbirth, as well as by ancient Romans and is used by present day orthodox Jewish women after menstruation as well as after childbirth.

Sexual intercourse is not permitted anywhere until the puerperium, however defined, is over. Mexicans, like so many others, believe that intercourse when there is vaginal bleeding is abhorrent. The Navajo believe that even indirect contact with vaginal blood is very dangerous to the husband and anyone else. In many cultures, contact with blood was considered polluting to the individual and to the community. The woman could now be purified, by bath and by religious ceremony. Leviticus XII, two provides the Laws of Purification and Atonement for Jews,

Christians, and Muslims. The postpartum bath is a Shinto rite of purification in Japan.

Non-Western Birth Today

It is estimated that worldwide, 80 % of births are attended by Traditional Midwives, Traditional Birth Attendants, or simply female relatives. The status of the traditional midwife has varied through time and place. For some non-Western cultures, her status has been very low, for it is women's work, and deals with blood. With many ethnic groups in India, midwifery was looked upon as a most degrading occupation.

The traditional midwife is typically a woman who is respected in her community, nonliterate, postmenopausal, has herself borne children, and learned her craft as an apprentice to another woman. She is often looked down on by the Western medical community. Traditional midwives may get Western training to meet difficult births, although they may not always find such instruction useful. When Western technology is not available, the traditional midwife's birth skills may prove to be superior. It may be hoped that the Certified Nurse Midwives of each culture may bridge the birth customs of the non-Western traditional midwife with the practices of Western biomedicine.

Childbirth in India

Nitin Trasi

Obstetrics in Ancient India

The oldest sources of information about Indian culture are the four *Vedas*, sacred compositions probably compiled over several centuries during the second millennium BCE. The knowledge about Vedic medicine is contained mainly in the fourth and latest Veda, the *Atharva Veda*, and a related later work, the *Kaushika Sūtra*. Later, in the post-Vedic era, the ancient Indian system of medicine acquired the name *Āyurveda* (lit.: knowledge of life). The golden age of Indian medicine lasted almost 2,000 years, from about 1000 BCE to about AD 1000. The most famous works written at this time were the

medical treatises known as the ► *Caraka Saṁhitā* and the *Śuśruta Saṁhitā*.

The art of obstetrics was well advanced in ancient India. Āyurveda had eight branches (*aśtāṅga āyurveda*), one of which was *Kaumārabhr̥tya* – gynecology, midwifery, and pediatrics. This included the classification of diseases of the female genital tract, including menstrual disturbances, and suggestions for treatment. It discussed the clinical course and various stages of labor, difficult labor (*mūḍagarbha*), the management of the puerperium (the period of confinement after labor), and miscarriage (*makkalla*). The different malpositions of the fetus were also known, and methods of treatment by version (the manual turning of the fetus to make delivery easier), embryotomy (an operation to destroy the fetus), forceps delivery, and even cesarean section were described (Keswani & Sharma, 1972). In fact, the first mention of the obstetric forceps in world literature is to be found in the Vedas. It was called the *jugna śankhu*, and consisted of paired, semicircular-ended tongs, such as that used for holding hot utensils. It was probably used for extracting a dead and dismembered fetus from the mother's womb (Das, 1929; Douglas & Stromme, 1988, p. 367).

Caraka, the author of the *Caraka Saṁhitā*, was a famous physician. He is believed to have been the court-physician of the Buddhist king Kaniśka (AD 78–100), and attended on the king's wife as obstetrician during her difficult delivery (Saletore, 1984, pp. 300–301). The *Caraka Saṁhitā* lacked a detailed study of surgery, but was otherwise quite comprehensive.

Śuśruta was the most celebrated surgeon of ancient India. The *Śuśruta Saṁhitā* was originally written probably in the last centuries BCE, although some date it much earlier, even as far back as 1000 BCE. It is especially important from a surgical point of view. Śuśruta mentions as many as 121 instruments of various descriptions, made largely of steel. Alcohol in the form of medicated wines was used as a narcotic during and also after operations, and hot oils, tar, or

caustics were used to stop bleeding. A drug called *Sammohinī* (producer of unconsciousness) was administered before major operations, and another drug, *Sanjīvanī* (restorer of life) was employed to resuscitate the patient after operation (Keswani 1961, 1967).

When delivery was impossible by natural means, the fetus – usually dead by then – was probably extracted using forceps; if necessary after dismemberment by embryotomy. Cesarean section, though mentioned in the literature, was not likely to have been a real choice. It had an extremely poor maternal outcome (almost 100 % mortality) the world over until the twentieth century. In ancient India too, it was probably only performed on rare occasions on a dying mother (or one who had just died) in an attempt to save the baby. Embryotomy, on the other hand, seems to have been a well-known procedure, finding mention even in nonmedical literature. The great monistic philosopher Ādi Śaṅkarācārya (AD 788?–820) refers to it, citing it as an example of human suffering even before life has begun.

If, by chance, the child moves into a transverse position at the time of delivery, it is then turned out (extracted) forcibly, broken into pieces by instruments (*Prabodasudhākara*, v. 10).

Charitable hospitals were established by many rulers, notably Rāhul, the son of the Buddha, and the famous Emperor Aśoka (ca. 273–232 BCE or 265–238 BCE).

The Populace

Although the art of obstetrics was well advanced in ancient India, most people probably had little access to it. Pregnancy and childbirth were generally managed at home, by practices based partly on experience and partly on cultural beliefs. Girls were customarily married off at a very young age, often even before they had attained puberty. Their obstetric career therefore began early, and they continued to bear as many offspring as their health would permit. The pregnant woman was subjected to many restrictions.

The solar and lunar eclipses were believed to be especially inauspicious times for her, and she was forbidden from venturing out into the open at these times.

Childbirth was largely a domestic affair, the parturient woman being attended to by experienced elder ladies from her own and from her neighbors' families. The squatting position or the seated (kneeling) posture was often favored for childbirth, and even today many tribal societies in India prefer these positions. The vaginal canal was lubricated with clarified butter (*ghī*) and *ghī* was also fed to the mother in the belief that it would lubricate the birth canal. A normal delivery did not usually present too many problems, but there was no recourse when complications arose, and in such cases the baby was often lost, and at times the mother too. Unsanitary conditions and lack of proper training and knowledge contributed to a high maternal and fetal mortality. Neonatal tetanus was an important cause of infant mortality. Cow dung was believed to have purifying properties, and was commonly used to "purify" the floor of the house (Saletore, 1943, p. 114). This could have been a contributory factor.

At some time, the system of the traditional birth attendant, the *dāi*, took root. These *dāis* were usually experienced elderly ladies who would provide their services for a modest fee. However, though experienced, the *dāis* had no scientific education or training. Even today, it is estimated that *dāis* conduct over 50 % of births in rural India. However, since 1957, the *dāis* undergo scientific training, and *dāi* training is now an essential part of the maternal and child health program of the Indian government.

The Medieval Ages and Later

With the coming of the Muslim conquerors to India, from the tenth century onward, the golden age of Āyurveda began to decline. Some of the factors leading to the decline were want of

patronage from the rulers, aversion of educated Hindus to contact with blood, pus and diseased persons, and absence of a system of regular education and training for practitioners. In the absence of professional standards, it became difficult to distinguish the genuine practitioners of Āyurveda (the *vaidya*'s) from quacks. Medicine in India during the later medieval period was dominated by Persian and Arabic influences which introduced an amalgam of Greek and Persian medicine, known as the *Unāni system* of medicine.

From the 1800s until 1947, the British ruled over most of India (British India included what are now India, Pakistan, and Bangladesh). By then, both Āyurveda and the *Unāni* systems were unorganized, as they had not kept up with modern discoveries and research. Skills were passed by familial succession and not by institutionalized education, and the practitioners were for the most part uneducated and unwilling to incorporate the new knowledge and discoveries that were pouring in from the West.

The state of public health in India at the time was poor, and women and infants were the most neglected segments of society in matters of medical aid. Maternal mortality (maternal death during childbirth) and infant mortality were very high. Even when modern medical treatment was available, resistance to treatment by male physicians and the strict *purdāh* system prevalent among certain communities often ensured that women got little access to it. There were cases where women preferred to die in childbirth rather than submit to treatment by a male doctor (Kumar, 1998).

Modern Obstetrics in India

The Portuguese first introduced modern Western medicine to India (Royal Hospital, Goa, 1510), but it was largely the British who later established and consolidated both its practice and its study in the subcontinent. Popularization of sound

surgical practice led to great improvements in the health of the population. Specialization was introduced in Indian universities both in education and research, and India was kept abreast of all the major developments taking place in the fields of science and medicine all over the world. All-women managed hospitals were opened for women patients. In Bombay (now Mumbai), several hospitals for women were opened in the late 1800s; among them, the Cama Hospital (1886) and the Allbless Obstetric Hospital (1890) were entirely managed by women staff. Medical education was promoted among girls even at a time when this was not popular in Europe. Anandibai Joshee was the first Indian woman to go abroad for medical education. She obtained an American degree in 1886. Significantly, her MD Dissertation topic was “Obstetrics among the Aryan Hindoos” (Kumar, 1998).

In the early twentieth century, several Indian obstetricians made valuable contributions in the field of obstetrics. Some of the pioneering Indian obstetricians were Dr. N. A. Purandare from Mumbai (1877–1964) and Rão Sāhib Dr. Shivarao Trasi (1881–1954) from southern India. In 1929, Sir Kedarnath Das published his work on the history of the obstetric forceps, which is still considered a classic, and in which he described over 500 varieties of forceps and included over 2,000 references in ten different languages. Dr. V. N. Shirodkar (1899–1971) pioneered several new surgical techniques, the most famous of which was an operation for women suffering from repeated abortions. Other leading obstetricians were Dr. K. M. Masani (1903–1988), Dr. M. K. Krishna Menon (1908–1988), and Dr. B. N. Purandare (1911–1990), among many others.

In India today, women use both traditional and modern techniques, depending on their location and income. In remote rural areas, conditions are similar to what they were a hundred years ago, while women in the city have access to top hospitals and the best of equipment. Mortality statistics are still alarmingly high in certain parts of the country.

Cities and Towns in Ancient Israel (Bronze and Iron Ages)

Avraham Faust

Bar-Ilan University, Ramat-Gan, Israel

Background

Many cities have been uncovered from Bronze and Iron Age Israel, the vast majority of which were located on *tells* – artificial mounds created as a result of gradual human settlement activity. Notably, not every location is suitable for the emergence of a center, even of a local nature, and each site had advantages and disadvantages in relation to factors such as security, water supply, transportation (roads), and the availability of soils for agriculture. Consequently, only several locations could, in antiquity, provide livelihood for a large population at any given region. This resulted in a repeating pattern in which the centers of many periods were continuously located one on top of the other, thus creating the famous tells which are so typical of the Middle Eastern landscape. Although in many instances extramural neighborhoods were built on the slopes of the tells (and in some rare instances cities were not built on tells), it is only in the later half of the first millennium BCE that the overall pattern changed. By then most *tells* were abandoned, and cities were built practically everywhere. The gradual process of tell abandonment resulted from many factors, including changes in security conditions, increased population, and improved technology, but this process lies outside the scope of the present discussion.

Notably, the towns (and tells) of ancient Israel were much smaller than their contemporaries in Mesopotamia and Syria. An average city of the Bronze and Iron Age covered some 3–5 ha (and sometimes even less); larger towns, in the scale of 7–12 ha, were also present. Towns of 20 ha, however, were exceptionally large, and megalopolises of 60 ha and more were extremely rare – very few such sites existed in the periods discussed here

(e.g., Hazor in the Middle Bronze Age II and Late Bronze Age and Jerusalem in the Iron Age II).

Defining a city is a complex enterprise. Within the scope of the present entry, suffice it to note that the urban centers were much larger and more crowded than their rural contemporaries. Their inhabitants were of diverse backgrounds and occupations, and not all of them were engaged in agriculture. Social stratification is evident in practically all such sites, along with public buildings and royal construction activities (palaces, walls, storehouses, water systems, etc.). These urban settlements served as political and economic centers for the villages that surrounded them and, probably also, during most periods, as centers of tax collection and as places of refuge in times of need.

History of Urbanization in Ancient Israel Up to the Persian Period

Cities first appeared in ancient Israel around the transition to the third millennium BCE (Early Bronze Age) (see section “[Extra 1](#)”). These first cities usually lie at the bottom of the tells, and in most cases not much is known for certain about their planning. It is mainly in the desert area, where the sites were not resettled in later periods, that we can discuss elements of city planning. ‘Arad, in southern Israel, is the best-known example of such sites (Fig. 1).

The site covers almost 10 ha and seems to have been divided into several public and residential quarters. The former included several small temples and a modest palace. A large, but simple, water system into which rainwater was collected was unearthed in the lowest part of the city. One should remember, however, that it is not certain whether ‘Arad is a representative of the Early Bronze Age urban phenomenon, as, due to its location on the desert fringe, it might have differed from the typical towns of the third millennium BCE.

The Early Bronze cities were gradually destroyed and abandoned toward the end of the millennium, and by the last two centuries

Cities and Towns in Ancient Israel (Bronze and Iron Ages),

Fig. 1 The Early Bronze Age city of 'Arad (Based on Kempinski, 1992a, p. 76; courtesy of the Israel Exploration Society)

of this millennium (the Intermediate Bronze Age) Cisjordan was devoid of any urban settlement.

Urbanization resumed in the twentieth and nineteenth century BCE (Middle Bronze Age II; 2000–1550 BCE). New cities emerged throughout the country, with an emphasis on the lower regions. Port cities were built for the first time. The largest Middle Bronze Age urban center was Hazor, which was apparently part of the Syrian system of city-states. Many sites were now surrounded with massive earthworks, whose purpose, however, is in doubt, since in many instances no city wall was unearthed on top of them. Some scholars have suggested that their construction, which required much labor but very few experts, served the local leaders as a substitute for the building of large and impressive city walls, as the latter would have required more experts who were not easily available for

most rulers. Some towns show signs of planning, probably following a simple grid (Tell el-‘Ajul) (Fig. 2).

While most characteristics of Middle Bronze Age culture continued during the Late Bronze Age (1550–1200 BCE), the number of towns declined, and they became smaller in size. Furthermore, hardly any settlement was fortified at the time (since the region was an Egyptian colony, the latter can probably be attributed to Egyptian policy).

Further decline occurred during the Iron Age I (1200–1000). The Egyptian domination over Canaan vanished, and many centers were destroyed or abandoned. Other towns, however, continued to exist, especially in the northern valleys, and a new wave of urbanization took place in the southern coastal plain, as a result of the arrival of the Sea Peoples (mainly the Philistines). The latter founded some new cities, for

Cities and Towns in Ancient Israel (Bronze and Iron Ages), Fig. 2 The Middle Bronze Age II center of Tell el 'Ajul (Based on Kempinski, 1992b, p. 124; courtesy of the Israel Exploration Society)

example, in Ekron, covering relatively large areas.

Urbanization in many parts of the country was gradually resumed only in tandem with the formation processes of the Israelite state, in the tenth century BCE, during the transition to the IAI (c. 970–586 BCE) (see section “[Extra 2](#)”). This urbanization probably involved, partially at least, forced settlement of population in urban centers.

The Iron Age II presents a settlement peak in the history of the region. Many urban centers were erected at the time throughout the country. Excavations have uncovered various types of cities and a complex settlement hierarchy. These range from capitals, through administrative and regional centers of different sizes, to small field towns (in addition to rural settlements of course). The largest cities of the period were Samaria and Jerusalem, the capitals of the kingdoms of Israel

and Judah (respectively). At its height, the latter covered some 90–100 ha (including extramural neighborhoods) – larger than any other site in ancient Israel during the Bronze and Iron Ages. Also of significant size were several Philistine centers such as Ekron, Gath, and Ashkelon.

Excavations have revealed clear evidence for socioeconomic stratification. Most of the population lived in small houses, which probably housed small nuclear families. The wealthy and some high officials were better off and lived in large four room houses (see section “[Extra 3](#)”). In some settlements, a form of a middle class is also identified. Palaces, which were identified in several cities, represent the upper part of the socioeconomic continuum, and this is where the royal family and the highest officials lived.

The Assyrian and (mainly) the Babylonian campaigns brought about large-scale destruction and population decline, and the number and size

of towns declined dramatically. Urbanization in the Persian Period was more limited and concentrated mainly in the coastal plain. Real large-scale urbanization reemerged only in the Hellenistic period.

Iron Age Town Planning

The Israelite towns of the Iron Age II (1000–586 BCE) have received a great deal of scholarly attention. This results from the interest of scholars in this part of the biblical period, from its being a demographic peak in which more sites existed than ever before, and because the Iron Age II usually comprises the upper strata on the tells, therefore permitting large-scale exposure, impossible for other periods.

According to Yigal Shiloh's seminal study, the basic outline of the Israelite "town plan is clear: alongside the line of fortifications there is a belt of buildings bordered on the inner side by a ring road, running parallel to the fortifications, and separating these structures from the 'core' of the city. The 'core' itself was divided into many blocks of residential units of the four-room house type and its subtypes" (Shiloh, 1978, pp. 37–38) (Fig. 3).

Apparently, the outer belt was intersected by small alleys, separating the various houses and leading to the city wall, therefore enabling free access to the wall and to its casemate rooms (when these existed) (Fig. 4).

While some components of this plan can be found throughout the kingdoms of Israel and Judah, it is more typical of the Kingdom of Judah (e.g., Beth Shemesh, Beersheba, Tell Beit Mirsim, and the recently excavated Kh. Qeiyafa). In most cities in the kingdom of Israel (and probably also Philistia), a different planning prevailed. Here the city wall was accompanied by a road, and only inside this street were buildings built, divided into quarters by smaller streets (e.g., Hazor and Megiddo).

Accessibility to the city wall seems to have been a major factor in Iron Age town planning. A besieged city which fell to the enemy suffered a horrible fate, and both types of planning

Schematic model of the Israelite city, based on Tell Beit Mirsim, Tell en-Nasbeh, Beth Shemesh and Beer-sheba: 1. fortifications; 2. buildings of the outer belt; 3. ring road; 4. central core.

Cities and Towns in Ancient Israel (Bronze and Iron Ages), Fig. 3 A typical Israelite town (According to Shiloh, 1978, p. 41; courtesy of the Israel Exploration Society)

enabled the defenders easy and quick access to the city walls, through the small alleys in the "Judahite" plan and from practically any place in the "Israelite" plan.

Another difference between Judah and Israel lies in the fact that most towns which were built according to the latter plan were surrounded by a solid wall, while the "Judahite" plan is usually accompanied by a casemate wall. The alleys constructed in Judahite towns enabled the authorities not only access to the top of the wall but also to some casemates, which could have been used for storage. The principle of accessibility to the city wall was adhered to in both plans, and it is likely that the reason for the adoption of different planning was due to space considerations. Larger cities could afford a massive wall and a street that ran along it. Smaller towns, in which space was scarce, tried to save as much area as possible. Casemate walls were therefore built, and the

Cities and Towns in Ancient Israel (Bronze and Iron Ages), Fig. 4 Part of Beth Shemesh city plan (Based on Shiloh, 1978, p. 40; courtesy of the Israel Exploration Society)

ring road was located inside the outer belt of houses (therefore reducing the space it consumed).

Another characteristic of the Iron Age city was a public quarter near the city gate. The impressive gate was usually accompanied by an open square, and near or around it were public structures, palaces, storehouses, barracks, water systems, etc., as can be seen in Beersheba, Tell en-Nasbeh, Beth Shemesh, Jerusalem, Kinrot, and Gezer (see section “[Extra 4](#)”).

Furthermore, cosmological principles had also an influence on Israelite construction on all levels, from dwellings to cities. It seems that as part of their complex cosmology the Israelites regarded the east as the most auspicious direction and the west as the most inauspicious one (like

many other societies). Accordingly, they directed their structures in an easterly orientation whenever this was possible, and when this was not the case, they, at least, attempted to avoid the west. This was manifested also in city gates, and about 75 % of those faced, roughly, the east. Following easterly orientation for dwellings in towns was difficult and was carried out in the following manner: (1) public buildings were adjacent to most of the Iron II city gates; (2) most city gates were oriented to the east.

The result was that no dwellings were built in the eastern part of the outer belt and no dwellings in this belt were expected to face the west, therefore avoiding this inauspicious orientation. The same principle was also followed inside the ring road, as in many cases houses were oriented

Cities and Towns in Ancient Israel (Bronze and Iron Ages), Fig. 5 General plan of Beer-Sheba (Singer-Avitz, 1996, p. 168; courtesy of Prof. Ze'ev Herzog, Tel Aviv University)

toward small alleys (and avoided the main street when it was to their west).

The eastern orientation seems, therefore, to have been a major principle of town planning, influencing not only the orientation of city gates but also of many dwellings and alleys.

The town of Beersheba is a good example of a planned settlement in the Iron Age (Fig. 5).

During the eighth century BCE, Beersheba (stratum II) was a small but well-planned administrative center in the Negev. Its gate was in the southeastern part of the wall, facing this direction. Inside the gate, a small square was located, surrounded by public buildings of various sorts. The city wall was accompanied with a belt of

houses, which used its casemates as their back-rooms, and with a nicely built inner ring road that gave access to these houses. The outer belt of houses was intersected in various points by small corridors that connected the ring road with the casemate walls, enabling easy access to the wall and to some of its casemates. The inner part of the town – its core – was divided by smaller streets which cut through it, dividing it into blocks of houses.

The eastern part of the outer belt of houses was composed of public buildings and did not include any dwellings. The dwellings in this belt, therefore, were oriented to the south, east, and north, but not to the west. Houses in the inner blocks

were oriented toward the inner streets, usually avoiding the west. Adhering to the eastern orientation caused them, in some instances, to orient their backs to the main street and to face small alleys.

Extra 1

Notably, the emergence of towns was a long process, and it is not always easy to identify the exact point in time from which a settlement should be called a city. Some settlements were quite large and complex already in the last phase of the fourth millennium BCE (Early Bronze Age I, traditionally regarded as a “proto-urban” period), and some have suggested that these were the first cities. Other scholars, however, questioned the validity of the term “urban” not only for the centers of the third millennium BCE but even for those of the later phases of the Bronze Age, suggesting that they were just complex villages. Most scholars, however, accept the traditional view and regard these large settlements as cities.

Extra 2

The transition from the Iron Age I to the Iron Age II witnessed the gradual disappearance of rural settlements in most parts of ancient Israel. It is suggested that at least part of this process resulted from a policy of “forced settlement.” The newly established Israelite monarchy transferred some of the population (especially in the newly conquered territories) to other/new settlements, and mainly to cities, in order to facilitate better control of the population, to lower costs, and to minimize the efforts involved in delivering sanctions, be it normative, remunerative, or coercive while maximizing its effectiveness.

Extra 3

The term “four-room house” is a convention used to designate the typical Iron Age dwelling in

ancient Israel whose ideal plan is composed of four main rooms. The typical house includes three parallel longitudinal spaces that are backed by a broad room, with the entrance located at the central longitudinal space. The “rooms” are really spaces/areas and can be subdivided. There are subtypes of the “ideal” form, comprising three or two “spaces” and, in exceptional cases, even five “spaces.” The high popularity of the four-room house was explained as either expressing its close relation with the Israelites (without elaborating the reasons for this relation) or its functional suitability to the needs of the Iron Age peasants, regardless of their ethnicity. Neither of these explanations, however, seem to account for the synchronic and diachronic dominance of the four-room house as a preferable architectural type in all levels of Iron Age settlement (from cities to hamlets; private dwellings and public buildings), all over the country (both in highlands and lowlands), for almost 600 years(!). It is likely that an adequate explanation for the unique phenomenon of the four-room house must relate to the ideological/cognitive realm and to its place within the Israelite social and spiritual worlds.

Extra 4

A typical public building in Iron Age towns is the “tripartite pillared building” (see Fig. 5, to the north of the gate). Such structures were discovered in many cities (especially near the city gate), but their interpretation varies greatly: the most common interpretation is that of a stable or a storehouse. In most instances, however, large quantities of domestic pottery (mainly bowls, jugs, juglets, cooking pots, and also storage jars) were found on the floors of these buildings. Since the finds do not easily fit with the above interpretation, some scholars have raised additional possibilities, including barracks, covered markets, customs house, and a multipurpose public building which had many functions, including a shelter for the poor.
